Acheson Furnace. The furnace invented by E. G. ACHESON [161] consists of a horizontal bed of refractory materials, furnace heads carrying the current load to the furnace, and long sidewalls made of concrete blocks, steel sheets, or steel grids. The bottom is cooled by air and loaded with a layer of insulating materials, e.g., granular silicon carbide, metallurgical coke, sand, or sawdust. The same materials are used for insulating the sidewalls and the surface of the furnace. Carbon black is used as an insulating material, especially if a lower ash content of the graphite product is desired (thermal purification). Carbon bodies that are to be graphitized are stacked between the furnace heads, usually horizontally and transversely to the flow of the electric current. The bodies are separated from each other and surrounded by a granular resistor medium, e.g., coke – graphite mixtures. Since the resistivity of the furnace depends essentially on the distance between the bodies and the packing density of the resistor material, the furnace must be carefully loaded. The capacity of Acheson furnaces is max. about 200 t.

The furnace heads consist of solid masonry with water-cooled graphite electrodes, which are connected by bus bars or shunts to transformers or rectifier transformers. The electric load is 0.1 – 1 MW/t. Because the resistance of the furnace decreases with the progressing graphitization, the voltage, usually between 50 and 250 V, must be reducible. The maximum current is ca. 100 kA. The power input is usually controlled by an empirical program since direct temperature measurement, especially at higher temperatures, is less precise [251]. Figure 29 illustrates the temperature changes during the graphitization process. The energy requirement of large furnaces is 3 – 4 kWh per kg of graphite material.

Acheson furnaces are firm constructions well-suited for the graphitization of all possible shapes and grades. Less satisfying

are the high energy demand, the relatively small production rate per square meter, the inhomogeneity of the product, and the difficulty of emission control.

Castner Furnace. This type of furnace, which was proposed by H. Y. CASTNER [160], does not contain granular resistor materials. One or more carbon artifacts are clamped between head electrodes, these forming the path for the heating current (lengthwise or longitudinal graphitization). One or both ends of the column are subjected to a mechanical or hydraulic pressure device to maintain a tight connection during the heating cycle. Insulation is similar to that of the Acheson furnace. Much higher heating rates are possible, and heat losses are accordingly smaller. The heating time can be less than 10 h, and the energy requirement is about 2 – 3 kWh per kg of graphite material [252]. In this process, the contact resistivity between the head electrodes and the abutting artifacts must be kept low by compensating for length changes of the column due to thermal expansion, puffing, and graphitization shrinkage. It is customary to insert sheets of a plastic temperature-resistant material between the abutting faces and push the faces against each other. Due to their small size, Castner furnaces are well-suited as mobile units on tracks and for moving to separate loading and unloading stations [253].

In addition to the lower energy requirement, the homogeneity of the product is also an impressive feature of this process. Less favorable is its limitation to certain sizes and grades.

Induction Furnace. Small induction furnaces have been used for several years for the graphitization of smaller carbon bodies [254]. The graphitization of large artifacts up to 2 m in diameter has also been studied. Induction furnaces make it possible to perform continuous graphitization. Although the electrical load of the induction coil is limited to about 2 MW, an adequate production rate and energy efficiency can be achieved. The frequency that is used depends on the specific electrical resistivity of the artifact and its diameter. The frequency for larger diameters is several hundred and for small diameters several thousand cycles per minute. The diameter of the induction coil must correspond to the diameter of the artifact. This is a considerable drawback of this method. By using separate susceptors or combining several shapes in a certain pattern to one unit, this problem may be eased [255].

Radiation Heating. Furnaces using thermal radiation from graphite heating elements are less sensitive to the size and grade of the carbon artifacts and are also suited for continuous graphitizing processes [256], [257]. The heating rate may be as high as 3000 K/h, and the energy requirement is about 2.5 kWh/kg without heat recovery. Since the temperature of the heating elements is obviously above 3000 °C, there is considerable vaporization of carbon (average loss about 10^{-6} g cm^{-2} s^{-1}). Therefore, the process is limited to smaller sizes.

Purification. Coke and binder materials used for the production of graphite artifacts contain various quantities of impurities. The impurities and contaminants of the artifacts resulting from production must be removed for some uses, e.g., nuclear graphite, spectroscopic carbons, etc. Thermal, thermochemical, and chemical purification processes must be differentiated. The graphitization process is itself a simple thermal process. Its efficiency may be increased by adding getter substances such as carbon black to the insulating material [258]. Gaseous halogens and halogen compounds are blown into the graphitizing furnace for further purification at temperatures above 1000 °C. They form volatile halogen compounds with nonvolatile impurities; this is known as the thermochemical process [259]. In another process, solid halides (e.g., NaF) are distributed in the graphitizing furnace and vaporized during heating [260]. The flue gases are cleaned in scrubbers with caustic soda solutions. Chemical purification processes were originally applied to natural graphite to remove gangue. The treatment of graphite ore with soda or fluorine is an example. Fine-grained natural graphite used in the manufacture of nuclear graphite is treated with alkali metal hydrogen fluorides [261]. The ash content of nuclear graphite grades is as high as several hundred mg/kg and that of spectroscopic carbons as low as 1 mg/kg.

Machining. Graphite is readily machinable. Lubricants or cutting fluids are not necessary. It can be sawed, turned, bored, drilled, planed, shaped, and milled. Surface roughness decreases in this sequence from ca. 25 – 125 to 1 – 6 µm. A fine-grained grade is always smoother due to the smaller pores revealed through cutting. The same machines are generally used as in metalworking. Tool speed and depth of cut are greater, while feed and cutting power are lower (5 – 30 N/mm^2 compared to ca. 2000 N/mm^2 for steel) [262]. The hardness of carbon grades is considerably greater than that of graphite grades, and the tool wear is about 100 times greater. Graphite electrodes for EDM and other complicated shapes are satisfactorily drilled with NC machines [263].

Graphite electrodes are frequently machined on production lines consisting of stations for turning the cylinder surface, as well as for cutting and grinding the threaded sockets and abutting surfaces. The connecting nipples are cut to length, bored, filled with pitch pins, and threaded [264]. Graphite apparatus and equipment are machined to precise specifications and often consist of numerous single sections which must be joined together. This is achieved with curable resin mixtures containing powderous carbon or graphite. Soldered joints are used to join carbon and graphite shapes to electrical conductors.

Impregnation and Surface Coating. About 25 % of the volume of carbon or graphite artifacts consist of pores which are sometimes detrimental to the bulk properties. The pores may be filled at least partially or closed by impregnation with a solid material whereby strength, conductivity, and resistance against oxidation are improved. Pitch is the most frequently used impregnating agent. Porous artifacts are charged in a vacuum autoclave after being preheated well above the softening point of the impregnating pitch. The autoclave is evacuated to remove the air from the pores of the artifact and is filled with molten coal tar pitch or petroleum pitch. The pressure is increased to ca. 1.0 MPa (10 bar). To pyrolyze the incorporated pitch, the impregnated artifacts must be heated to ca. 800 °C, a process known as rebaking. Impregnated artifacts have a higher bulk density and, therefore, improved strength and conductivity. Emission control of vaporous pitch components during impregnation requires special provisions [265]. Artifacts are generally impregnated and rebaked before graphitization. The coke that has been incorporated into the pores becomes porous, and the artifact again becomes permeable a result of pyrolysis. For impermeable artifacts, e.g., for nuclear fuel elements, impregnation must be repeated several times [266].

Graphite grades used at lower temperatures may be impregnated with curable resins, particularly phenol – aldehyde and furan resins. The tolerated application temperature of these grades is at the most ca. 200 °C. Since these resins are resistant to corrosion, the impermeable material is widely used for the production of heat exchangers and other chemical apparatus

[267]. When polytetrafluoroethylene wax is used as an impregnating medium, the application temperature can be raised above 200 °C [268].

The pores of carbon and graphite bodies may also be impregnated with carbon formed by chemical vapor deposition (CVD) processes [269]. The rate of deposit is limited, since otherwise only pyrocarbon would be deposited on the outer surface of the artifact [270]. Carbon and graphite bodies are impregnated for special effects with lubricants (brushes), metals (bearings), and oxidation inhibitors, e.g., phosphates and borates [271].

Coating the surface of carbon and graphite artifacts with refractory materials, e.g., carbides, silicides, borides, or nitrides, also protects against oxidation. Coatings are brushed or sprayed onto the surface, and the deposited layer is sintered, or the coating is applied by flame or plasma spraying, chemical vapor deposition (CVD), or physical vapor deposition (PVD) [272].

Emission Control. The most important emissions during production of carbon and graphite products are coke dust (crushing, machining), coal tar pitch volatiles (mixing, baking, impregnating), and sulfur dioxide (graphitizing). Of primary hygienic concern are the high-molecular-mass polycyclic compounds which are present in the air as aerosols [273]. Particulate emissions are limited to 75 mg/m^3 including 50 mg/m^3 tarry substances at the most [274].

Current Problems. As with other materials, the production of graphite faces three major problems: energy requirements, increased product quality, and environmental protection. The production of 1 t of graphite requires ca. 2.6 t of fuel oil; the heat content of graphite together with auxiliary materials equals that of ca. 1.9 t of fuel oil, amounting to a total of 4.5 t [275]. The production of graphite is, therefore, very sensitive to the oil supply. Efforts must be made to minimize this dependency. Only a fraction of this amount of energy is on disposal (Table 7). The energy requirement could be decreased considerably by continuous baking and graphitizing processes, which are more energy efficient. These processes would also facilitate energy recovery as well as the handling of the material and product [276].

Table 7. Energy requirements (GJ/t)

Baking	
Single-chamber furnace	6 – 15
Ring furnace,	
open	4 – 10

Graphitization	
Acheson furnace	11 – 15
Castner furnace	7 – 11

During the past decades, the demand for carbon and graphite products has increased considerably. Product quality needed to be, and must be still further, improved by applying advanced raw materials and decreasing the variation in processing, e.g., by developing continuous production processes.

4.1.2. *Properties*

Artificial graphite bodies differ more or less from the graphite single crystal. This difference is due to structural disorder, imperfect alignment, and porosity. Other parameters influencing the properties of graphite artifacts are the size and size distribution of the coke grains, the shape of the grains, the pore size distribution, the interaction between the components, and the content of impurities. Each parameter can be changed through the selection of raw materials and production methods. For instance, needle coke consists of highly ordered and aligned crystallites, regular petroleum coke is less ordered, and carbon black products are not ordered at all. The anisotropy of graphite artifacts containing these raw materials decreases in that sequence. The alignment of anisometric grains is also influenced by the forming methods. Anisometric particles are more perfectly aligned by the extrusion process than by vibration compacting. The microporosity of the artifacts that is developed during cooling from graphitizing temperatures affects the strength and thermal expansion [277].

Physical Properties. The variability of carbon and graphite products is illustrated in Table 8. The mechanical properties are similar to those of ceramic materials, whereas the thermal conductivity and electrical resistivity correspond to those of metals.

Table 8. Properties of carbon and graphite products (with grain)

Carbon block for furnace linings	Carbon anode	Graphite electrode		Graphite die for continuous casting	Resin-impregnated graphite for chemical application	Glassy carbon	Carbon fiber (HM)
		normal	UHP

The unique combination of refractory and metallic properties is useful for electrothermal and electrolytic processes performed at higher temperatures. In progressively loaded graphite artifacts, a rising number of microcracks is generated, propagating preferentially normal to the applied stress and causing relief of internal stress. The propagation of the cracks is restricted by pores or structural elements which are orientated transversely to the direction of propagation. When through linking of microcracks a critical crack length is reached macrofailure will occur. A model of fracture and stress distribution depending on microstructural features is described in [278]. Macroscopically, the Weibull approach can be used to give a reasonable prediction of failure. The fracture toughness K^c of common graphite grades is about 1 – 15 $MN/m^{3/2}$ [279], [280].

Graphite is a semimetal, in which the highest filled valence band overlaps the lowest empty conduction band [281]. There is no simple relationship between the conductivity of single graphite crystals and that of polygranular artifacts. The resistivity (with grain) of the latter is more than 20 times greater than that of a single crystal (in the *a* direction), and it decreases with temperature up to ca. 350 °C for graphite grades and up to ca. 1000 °C for carbon grades. The sign of the temperature coefficient of resistivity changes above these temperatures due to the fact that increased scattering of the charge carriers compensates their rising number in the conduction band. The thermal conductivity of carbon and graphite artifacts is determined by photon scattering at the crystal boundaries [282]. Conductivity is at its maximum at about room temperature. More informative for users of carbon and graphite artifacts may be the change of these properties with temperature. Strength and Young's modulus of graphite artifacts reach a maximum at temperatures of ca. 2500 °C, where they are ca. 50 – 100 % larger than at room temperature. Above 1400 °C, the specific strength (strength/density) of graphite is better than that of metals and most other refractory materials. The coefficient of emissivity amounts to ca. 0.8 – 0.9. The temperature dependence of strength and several other properties is illustrated in Figure 30. Types used at high temperatures are often exposed to sudden temperature changes or large temperature gradients, both inducing mechanical stresses. Table 9 shows the favorable thermal-stress-resistance factor *R′* of graphite compared to that of several refractory materials.

$$R' = \frac{k\sigma}{(1-\mu)E\alpha}$$

where k = thermal conductivity, μ = Poisson's number, E = Young's modulus, α = coefficient of thermal expansion, and σ = tensile strength.

Table 9. Average thermal-stress-resistance factor *R′* (W/m)

Figure 30. Relative properties of polygranular graphite grades vs. temperature (schematic)

CTE = coefficient of thermal expansion; c_p = specific heat; σ = tensile strength; k = thermal conductivity; ϱ = electrical resistivity

Chemical Properties. Carbon and graphite products are resistant to most corrosive substances, except strong oxidants, substances forming intercalation compounds, and carbide-forming substances [283]. At higher temperatures, graphite is, in fact, less reactive to oxygen than most metals. Since the reaction products CO_2 and CO are volatile, no protective oxide film can be formed. The reactivity depends primarily on the degree of crystalline order. The binder phase, which is normally less ordered, is preferably attacked. At lower temperatures, the reaction is not limited to the outer surface of the artifact but includes practically the entire inner surface, due to pore diffusion. With increasing temperature, the depth of the reaction zone decreases. In air, the average loss of small graphite artifacts in the temperature range between 500 and 600 °C is ca. 1 % per day. Impurities such as alkali metals, vanadium, and lead accelerate the reaction rate considerably. However, most carbon and graphite products are used at high temperatures in oxygen-containing atmospheres. The burn-off at these conditions may be decreased by impermeable protective coatings, e.g., carbides or silicides, or by the addition of substances which inhibit oxidation [272].

Other properties that are important to special applications of carbon and graphite products, e.g., lubrication properties, are described in Section Applications.

4.1.3. *Applications*

Carbon and graphite artifacts are mainly used in metallurgy, electrochemistry, chemistry, and mechanical and electrical engineering.

Electrodes for Arc Furnaces. About 90 % of the graphite products are electrodes used for the production of electric arc furnace steel. The production of electric steel has been increased by the rise in productivity, the development of small steel works (mini mills), and direct reduction methods (DR) supplying the electric furnaces with processing materials other than scrap. The addition of thin-slab casting to mini mills has opened up new appllications in the automotive industry. In 1999, electric furnaces accounted for some 33 % of the worldwide raw steel output, as opposed to to 25 % in 1989. Graphite electrodes were required to meet the rising demands of increased electric load up to ca. 30 A/cm^2.

Graphite electrodes up to 750 mm in diameter consist of cylindrical sections up to 2700 mm in length, which are joined with tapered, threaded nipples. High-accuracy machining is a prerequisite for a well-functioning joint. The screw joint is secured by pitch or resin cement bridges. This material is stored in the recesses of the nipple and flows when the electrodes are heated in at least part of the thread clearance. At higher temperatures, the cement carbonizes and prevents the electrode sections from loosening [284], [285]. The surface temperature of the electrode increases along the entire length of the electrode to 2300 – 2800 °C [286]. The burn-off through oxidation is proportional to the surface area and is ca. 5 kg m^{-2} h^{-1} at normal operating conditions [287]. Carbon is also vaporized from the arc spot at the tip of the electrode. The loss is proportional to I^2 (I = electric current). Accidental sources of loss are breakages of the electrode sections. Depending on the operating conditions, the specific graphite consumption is approximately 1.5 – 3.5 kg per tonne of steel. With D.C. furnaces consumption figures of < 1 kg of graphite per tonne of steel have been achieved. Surface and tip losses range between 30 and 70 % each. The relative breakage loss is ca. 5 – 20 %. Figure 31 shows graphite electrodes removed during recharging of an arc furnace.

Figure 31. Withdrawn graphite electrodes during recharging of the arc furnace

To reduce oxidation losses, the electrode surface can be coated with refractories and oxidation-resistant metals [288], [289]. For the same reason, water-cooled electrode systems have been introduced. In such a system, the upper section of the electrode consists of a water-cooled metal cylinder instead of graphite [290], [291]. The tip losses can be reduced by using longer arcs and weaker current. The breakage losses caused by stresses due to temperature changes and by bending moments due to scrap motions and vibration are decreased by using high-quality electrodes (low electrical resistivity and high thermal shock resistance and flexural strength) and relieving the stress. The electrodes can be upgraded by using selected needle coke grades and impregnating the electrodes with pitch. In general, breakage losses of impregnated electrodes are only about one-third of that for nonimpregnated types. Severe thermal stresses are induced in the joint components — nipple and electrode socket — due to the difference in properties of these components [292], [293]. To avoid any undue increase in thermal stresses, the stress must be relieved by special shaping of the joint and its clearance [294], [295]. It was also proposed to relieve stresses in the electrode section, e.g., by slotting the electrode and even the nipple [296]. Cost-saving measures will focus on a further reduction in power-on times, which can be achieved by scrap preheating, post-combustion of CO, and increased injection of oxygen and coal. These measures will require improved stability of the graphite electrode material.

Electrodes for Electrothermal Reduction Furnaces. Electrothermal reduction furnaces are used for the production of calcium carbide, ferroalloys, phosphorus, silicon, and refractory oxides. Due to the relatively low current of ca. 6 – 10 A/cm^2, adequate results can be achieved with carbon electrodes, particularly Söderberg electrodes (self-baking electrodes). Söderberg electrodes consist of a sheet metal casing that is filled with a pasty mixture of electrode raw materials. The lower part of the electrode is baked by the excess furnace heat. In accordance with the consumption rate of the electrode — ca. 20 – 30 kg per ton of product — the electrode is lowered stepwise, a new casing sheet is joined to the upper part, the casing is filled with the mixture, and the middle section is baked. Hollow electrodes enable central charging, which in turn improves furnace operation [298]. Baked carbon electrodes consist of several sections that are connected by threaded joints. One end

of each section is nipple-shaped, while the other end is socket-shaped with an appropriate thread. Due to their higher electric conductivity, semigraphite electrodes are also used for reduction furnaces, especially for the production of silicon [299]. The combination of a graphite core surrounded by Söderberg paste has also gained market shares [297]. Electrodes for the fusion of tap holes generally consist of graphite.

Electrodes for Molten Salt Electrolysis. Carbon anodes and cathodes are used for the electrolytic production of aluminum. The anodes are partially submerged into a cryolite melt containing several percent of alumina. During electrolysis, the anodically produced oxygen reacts with the anode material and CO and CO_2 are formed. The ratio CO_2 : CO determines the current efficiency. Due to the operation temperature of 950 – 970 °C, the parts of the anode extending out of the melt are attacked by oxygen in the air. Consumption greatly depends on the properties of the carbon anodes, especially their permeability and reactivity, which are a function of the structural disorder and the impurities catalyzing oxidation, e.g., alkali metals [300]. As in reduction furnaces, Söderberg anodes are used in addition to prebaked anodes, which are now favored, since the waste gas of furnaces operated with prebaked anodes does not contain tars and other pyrolysis products, which complicate the gas cleaning. The average consumption of prebaked anodes is ca. 0.47 kg per kg of Al (theoretically 0.33 kg per kg of Al), and that of Söderberg anodes is ca. 0.55 kg per kg of Al. The difference is partially due to the baking loss when the Söderberg mixture is carbonized. Current supply rods are connected to the anode by carbon-containing cements or metal solders. The edge length of the anodes is up to 1500 mm (Fig. 32).

Figure 32. Carbon anode

The bottom and sidewalls of the Héroult–Hall cells, which protect the pot and the ceramic insulation against the cryolite melt, also consist of carbon material. Carbon blocks that form the bottom have longitudinal grooves in which cathodic bus bars are inserted. Bars and carbon blocks are joined in a manner similar to the anodic current supply rods. The joint between neighboring carbon blocks needs special attention. Different joining methods have been developed using special cements [301]. Cell life depends almost exclusively on the resistance of the carbon bottom. During operation, sodium and aluminum penetrate the carbon blocks, thereby forming intercalation compounds and aluminum carbide, which results in swelling and crack formation. These reactions are probably responsible for the long-term upheaval of the carbon bottom and the penetration of molten aluminum into the bus bars [302]. Both effects determine the cell's lifetime. Some reliable tests are available for predicting the serviceability of carbon grades [303]. If semigraphite blocks are used and the width of the joints is reduced, cell lifetime is increased to more than 3000 d [304]. Therefore, anthracite cathodes are increasingly being replaced by semigraphite or semigraphitized cathodes.

Due to its better resistance to chlorine, graphite anodes instead of carbon anodes are used in processes requiring molten chloride-containing electrolytes. The winning of aluminum from aluminum chloride melts [305], of alkali and alkaline-earth metals, of rare-earth metals, and of fluorine are examples. The anodes have often complicated shapes, e.g., slotted, hollow cylinders. Even though graphite reacts with fluorine in alkali fluoride melts, the lifetime of graphite anodes is adequate due to the formation of CF_x layers on its surface.

Electrodes for Aqueous Electrolysis. During the past decades, titanium anodes have been almost completely substituted for graphite anodes. Titanium anodes that are activated with platinum or a platinum compound often achieve a lower overvoltage than graphite anodes and do not “burn off” in the presence of oxygen-containing reaction products. Accordingly the use of graphite anodes for chlorine, chlorate, and hydrochloric acid electrolysis, for the production of manganese dioxide and hydrogen peroxide, for electrolytic pickling and polishing processes, and for protection against cathodic corrosion is decreasing. Electrodes for electroorganic synthesis are less affected [306].

Linings, Casting Molds. Due to their temperature resistance and their resistance to most metal melts and slags, carbon and graphite blocks are widely used as a lining for metallurgical furnaces. For use in blast furnaces, resistance to alkali attack and wear is required. For each refractory material, a critical temperature, which must not be exceeded during furnace operation, has been defined. To obtain sufficient lifetime from the lining carbon, grades with high critical temperature should be used (refractory approach), or the cooling of the lining must be increased by using semigraphite or graphite grades (thermal approach) [307]. The actual thermal and mechanical load of each part of the furnace must be calculated before the appropriate lining materials are selected. In Europe, the linings usually consist of large bricks (e.g., 600×800×2600 mm), in the United States smaller bricks are preferred. The number of joints can be reduced in the first case, whereas smaller bricks can be more easily adapted to the shape of the furnace. Carbon, semigraphite, and graphite linings are limited to the lower stack, bosh, hearth, and the bottom, whose life expectancy has been increased to more than 10 years. Lining and steel jacket are thermally coupled by a carbonaceous ramming mass with the necessary thermal conductivity. Other shaft furnaces with carbon linings are used for the production of ferroalloys, carbides, corundum, phosphorus, as well as melting furnaces for slag and zinc, and cupola furnaces.

Due to its thermal conductivity, thermal shock resistance, and low wettability by molten metals and slags — the wetting angle for most metals is 120 – 140° — graphite is an outstanding material for foundry molds, ingot molds, and crucibles for the casting of aluminum, magnesium, iron, steel, copper, brass, bronze, and other metals [308]. Continuous casting devices for steel generally consist of materials containing natural graphite and corundum. For nonferrous metals, high-density and high-strength graphite grades are used. Railway wheels are die cast in graphite dies. The station time is about 1 min and the die requires slight refinishing only after about one hundred casts [309]. Graphite molds are also used for precision casting [310]. All molds must have a smooth surface and must be uniformly permeable.

Graphite is also used for the production of cemented carbide and diamond tools, such as die, boat, crucible, and auxiliary devices for the production of semiconductor materials [311], for the refining of metal melts by feeding gases into the melt, and as a resistance heating element. Granular carbon and graphite are common resistor materials in Acheson furnaces for the production of graphite and silicon carbide. The resistivity depends on the packing density, which may vary to a great extent. Graphite rods, tubes, or slotted hollow cylinders have a more uniform resistance and are, therefore, preferred as heating elements for most other furnaces [312]. Graphite heating elements must be used in an inert atmosphere or under vacuum, keeping in mind that the vapor pressure of carbon is ca. 0.5 kPa at 3000 °C.

Process Equipment. One outstanding property of carbon and graphite is their resistance to corrosion. Graphite also has a relatively high thermal conductivity and is an interesting material for heat exchangers and chemical equipment provided that its permeability can be considerably reduced. The sealing of graphite artifacts is achieved by impregnation, especially with thermosetting resins such as phenol aldehyde or furfuryl alcohol resins. The permeability of impermeable graphite grades is less than 10^{-8} cm^2/s. The temperature at which it can be used is, of course, restricted by the decomposition temperature of the resins, but the limit of 200 °C is adequate for most chemical processes. To reach a higher application temperature, the impregnating media must be transformed into carbon and the loss of pyrolysis products must be compensated by a second impregnation and carbonization, etc. Usually two repetitions are needed for an impermeable allcarbon shape. The same result can be achieved by depositing pyrocarbon into the pores.

Examples of impervious carbon and graphite grades are absorbers, columns, heat exchangers, pumps, valves, pipes, fittings, towers, tower packing, and rupture disks (Table 10) [313]. Contrasted with metals, stresses are only dissipated by microfracture. Stress peaks must be carefully avoided through proper design [314]. This is especially true for all joints. The permissible operation pressure can be increased by fiber-reinforced types [315] and erosion resistance by certain coatings [316]. Standard quality is guaranteed through strict and extensive inspection.

Table 10. Carbon and graphite processing equipment

Equipment*	Max. size		Max. pressure (MPa)	Favored application
1. Heat exchanger				
Shell and tube	length	10 m	0.6 (1.2)	large heat exchange areas;
heat exchanger	diameter	2 m		fouling and encrusting substances
	exchange area	1000 m^2		
Block heat exchanger	length	9 m	0.6 (1.5)	smaller heat exchange areas;
	diameter	1.5 m		narrow spaces; high heat transfer rates
	exchange area	500 m^2		
Plate heat exchanger	length	2.3 m	0.8	high transfer rates; small pressure drops;
	width	0.7 m		small temperature differences
	length	2.5 m		
	exchange area	50 m^2

5. Centrifugal pumps	400 m^3/h		1.1	booster pump for corrosive liquids

* Maximum temperature: pos. 1, 200 °C; pos. 2 and 5, 180 °C; pos. 3 and 4, 350 °C.

Nuclear Reactors. Carbon has a low absorption cross-section for thermal neutrons and a favorable moderation coefficient. Since Fermi's Chicago pile reactor, graphite has been used successfully as a moderator and reflector material for gas-cooled reactors. The operation temperature is limited by the nature of the cooling media and is far lower for CO_2-cooled Magnox reactors than for helium-cooled high-temperature reactors (HTR). The neutron absorption cross-section is particularly

affected by such impurities as boron and rare-earth metals, which must be reduced by purification. The material must be processed under “clean conditions” [163]. During neutron irradiation, graphite undergoes considerable dimensional changes, which depend on structural disorder and the coefficient of anisotropy. The degree of damage can be considerably reduced through selection of raw materials and processing conditions [317]. The dimensional changes of the structural elements of graphite during the lifetime of an HTR are now small enough to be compensated by structural design.

Mechanical Engineering Applications. The self-lubricating characteristic of carbon is a fundamental property. The coefficient of static friction is ca. 0.1 – 0.25 at normal humidity. Carbon and graphite are, therefore, widely used as mechanical seals and bearings if the use of lubricants is not possible due to contamination (food), contact by aggressive substances (chemical industry), or operation at high temperatures. Carbon and graphite radial and axial bearings and bushings are used, for example, in immersed pumps and circulation pumps for feed water and cooling fluids. These bearings do not require maintenance for years [318]. Carbon and graphite sealing rings are used to prevent fluid leakage along rotating shafts and vanes [319]. Graphite and carbon vanes are used in rotary compressors and pumps. Depending on the different heat conductivity requirements, wear resistance, and mechanical load, the samples are usually either impregnated with resins, glasses, or metals (babbit, antimony, silver), or coated with resistant silicon carbide by reacting silicon or silicon monoxide with the carbon [320].

Miscellaneous Electrical Applications. Carbon and graphite are classical materials for electric contacts and electrodes whose range of application has been considerably expanded. Arc light carbons had a comparatively short history as a street illuminant. They are now almost exclusively used in film projectors. Color, temperature, and brightness have been improved by the introduction of carbons consisting of a carbon shell and a core containing alkali salts and rare-earth metal compounds [321]. Further developments of arc light carbons are arc cutting and welding rods. The arc cutting and gouging process requires the striking of an arc between the carbon electrode and a metal workpiece. A high-velocity air stream is directed to the base of the arc blowing the molten metal from the workpiece. The operation velocity depends on the electric power and the geometry of the air streams [322]. Welding carbons are preferred for spot-welding sheet metal.

For spectroscopic emission analysis, the sample is vaporized and the atoms are excited in an arc between two carbon electrodes. These electrodes tolerate only little contamination, which is also true for crucibles and boats used in atomic absorption spectroscopy. The electrically heated, mostly tubular crucibles are often coated with an impermeable pyrographite layer which is roughened to increase its reactivity [323]. Graphite tool electrodes are juxtaposed with a workpiece in an electric-discharge machine (EDM), both immersed in a dielectric liquid. The workpiece is eroded by a series of electric pulses. The graphite electrode loss decreases with the rising bulk density of the graphite grade. The smoothness of the eroded surface depends on grain and pore size of the electrode [324]. The size of EDM electrodes, which can be easily machined, ranges between a few millimeters and more than 1 m.

Graphite electrodes are also used as anodes for mercury-vapor rectifiers and power tubes. Sparking can be avoided if the electrode consists of high-density graphite grades which were heat treated under vacuum at temperatures above 2000 °C [325]. Graphite grids for high-power electron tubes improve their power handling capacity [326].

Carbon is applied in various types of primary batteries (battery carbon) and fuel cells. Particularly fuel cells have gained renewed interest for automotive and stationary applications. Carbon does not enter into the cell reactions, but acts as a corrosion-resistant conductor, as an electrocatalyst in air-consuming electrodes, and as a catalyst carrier [327]. In Leclanché cells, the carbon rod is surrounded by a depolarizing mixture containing MnO_2 and graphite powder or carbon black. The rod is often impregnated with waxes or fats to prevent evaporation of the electrolyte and permit the diffusion of gases. Leak proof cells are provided with additional seals.

Stacked carbon plates or disks are used as pressure-sensitive pile resistors. Examples are voltage regulators for sewing machines and illumination equipment. The high contact resistance of carbon granules, their invariability against atmospheric conditions, and the reproducibility of the resistance – pressure curve make carbon granules a satisfactory material for microphones. The granules are often stabilized by pretreatment through vibration or surface oxidation. Carbon diaphragms improve the frequency response with these granules (microphone carbon).

Carbon and graphite are important materials for use as electrical contacts. Carbon contacts have an excellent arc resistivity, they neither weld nor form isolating oxide films. Examples of stationary contacts are switches and circuit breakers for sliding contacts, as well as brushes and current collectors for trolley shoes and wheels [328]. Pantograph shoes are sliding contacts that transfer electric energy from a wire or rail to a moving device (vehicle). Carbon shoes spare trolley cables, wear slowly, have adequate resistance to impact, and cause little radio interference. The shoes are adjusted to special pantographs which maintain nearly constant contact pressure. Examples are electric locomotives (engines), tramways, trolley busses, and mobile cranes.

In most electric motors and generators, the revolving part of the machine and the stationary part are electrically connected by brushes. Brushes must be able to “absorb” the roughness of the commutator or slip ring surface, control film formation on the metallic counterpart, and absorb current pulses which result during current reversal (commutation). The diversified requirements are satisfied by numerous brush grades which can be adjusted to the various operating conditions. Typical examples are the following:

1. Carbon brushes with good polishing properties (for small electrical loads and circumferential speeds)
2. Soft natural graphite brushes with a great damping decrement (for high circumferential speeds)
3. Carbon – graphite brushes with good commutation properties (for small machines)
4. Resin-bonded graphite brushes (for machines with high commutation loads and average circumferential speeds, fractional horsepower brushes)
5. Impregnated electrographite brushes (power and industrial brushes)
6. Copper – graphite brushes (for machines with high electrical loads, automotive DC starter brushes)
7. Brushes containing lubricants for high-altitude use (aircraft and aerospace brushes)

4.1.4. *Economic Aspects*

By far the largest quantity of carbon and graphite products is used as carbon anodes in the aluminum industry and graphite electrodes in the steel industry, respectively. The average anode requirement is about 500 kg per ton of aluminum and that of graphite electrodes is 1.5 – 3.5 kg per ton of steel, both with decreasing tendency. The calculated consumption rate is shown in Table 11. The carbon and graphite requirement for other uses is much smaller, probably less than 15 % of the quantities shown in Table 11.

Table 11. Consumption of carbon anodes and graphite electrodes (in 10^3 t)

Year	Carbon anodes for aluminum electrolysis				Graphite electrodes for electric steel production			
	World	USA	Japan	Germany	World	USA	Japan	Germany
1950	750	220	10	14	116	38	5	2
1960	2260	900	65	84	294	58	30	15
1970	5150	1800	360	152	645	124	102	30
1980	8200	2300	550	365	1000	186	125	37
1985	7700	2900	110	380	1000	133	110	33
1999	12 500	1900	10	225	930	140	70	30

4.2. Other Classes of Carbon

Carbon and graphite products described in Section Carbon and Graphite Artifacts consist of an agglomeration of single carbon particles and can be regarded as a polygranular structure. Industrially important products have been manufactured from essentially monogranular carbon materials [329]. Carbon fibers are an important member of this group (⟶ Fibers, 5. Synthetic Inorganic).

4.2.1. *Glassy Carbon*

Glassy carbon is formed by pyrolysis of thermosetting resins, e.g., phenol, formaldehyde, furan, polyimide, and polyphenylene resins. The use of cellulosic or hemicellulosic materials as a precursor is less common [330]. For the production of glassy carbon artifacts, liquid resins are poured into molds, dry resins are molded or extruded, and the shapes are heat treated first for curing and then for pyrolysis. Porosity and pore diameter of the thermoset resins are very small, which complicates the diffusion of gaseous pyrolysis products. Although the heating rate during this process is small, the permissible thickness of the artifacts is at most 5 mm. Material shrinkage due to a mass loss of ca. 40 % during pyrolysis is also a restricting factor [331].

Glassy carbon is impermeable to liquids and gases and its fracture exhibits glossy shell-like planes. The highly disordered structure consists of a network of branched and twisted ribbons and microfibrils, which are interconnected at several points with an average height and length of ca. 3 and 10 nm, respectively. The ribbons surround micropores of 5 – 10 nm diameter, and the total porosity is ca. 40 % [332]. It is possible to produce glassy carbon grades with a specific BET surface and pore diameter by selected raw materials and heat treatment. These products are useful as molecular sieves or microfilters [333].

Due to its cross-linked microstructure, glassy carbon is isotropic and stronger and harder than polygranular carbon grades. The oxidation rate is considerably lower, since most pores are not accessible to reagents. These properties are advantageous for laboratory equipment, e.g., crucibles, boats, bowls, trays, and tubes for evaporation and smelting, as well as for the decomposition of materials for chemical and spectroscopic analysis (Fig. 33). Resistance-heated tubes are used in atomic absorption spectroscopy, molds for glass forming, electrodes for organic electrochemical synthesis, and other shapes for numerous other uses [335-337]. Due to its compatibility with human tissue, glassy carbon has also been successfully used for implants, e.g., bile ducts, and as stimulating electrodes for cardiac pacemakers [338], [339].

Figure 33. Laboratory equipment made of glassy carbon [334]

The carbonization of foamed resins, which are either thermoset or thermally stabilized by cyclization, yields foamed carbon. In particular, phenolic and polyurethane foams, hollow microspheres consisting of the same material, or thermally stabilized pitch are the initial raw materials [340], [341]. The latter must be mixed with a binder before carbonization. The thermal treatment is the same as for the production of normal glassy carbon. The carbon foam consists of a network of thin carbon cell walls (several micrometers) which surround comparatively large pores. The bulk density of carbon foam is less than 0.1 g/cm^3, and the thermal resistance is, therefore, almost as low as that of foamed resins. Carbon foam differs from these materials in that it can be used at temperatures in excess of 3000 °C, provided that oxidative atmospheres are excluded.

Foamed glassy carbon is an excellent insulating material for high-temperature furnaces, e.g., vacuum sinter furnaces or carburation furnaces. Above ca. 2000 °C, it is advisable to cool the insulation from the outside to reduce energy loss through radiation. Other uses are casting cores, substrates for catalysts, porous electrodes, and filters.

4.2.2. *Pyrocarbon and Pyrographite*

Pyrocarbon and pyrographite are products of the decomposition of gaseous carbon-containing compounds, a process called chemical vapor deposition (CVD). Parameters influencing this process are the type and concentration of the carbon donor, the temperature of pyrolysis, contact time, and gas flow [162]. Hydrocarbon compounds are favored as reaction gases, especially methane, propane, and propylene. At low temperature and low concentration, the deposited pyrocarbon layers have a laminar structure. At high concentration and a low temperature gradient, the gas is supersaturated and optically isotropic layers are formed. High temperature and low partial pressure promotes the formation of granular and columnar microstructures. The pyrocarbon is deposited on substrates, which have the contour of the desired final body. The deposition rate is ca. 10 – 2000 µm/h. The bulk density depends primarily on the deposition temperature; it is lowest at temperatures of ca. 1400 °C (1.3 g/cm^3) and increases to ca. 2.23 g/cm^3 at 2700 °C. Due to structural variation, it is possible to adjust the coefficient of thermal expansion of the layer to that of the substrate, thereby minimizing stresses caused by temperature gradients.

Highly oriented pyrographite (HOPG) is obtained by thermal or stress annealing of pyrolytic carbons [342]. This process decreases the proportion of disordered layers considerably. Interlayer spacing, which is the distance between the single graphite layer planes, can be as low as 0.3354 nm. Accordingly, the properties of this type of pyrographite are similar to a single graphite crystal. HOPG plates are used as flat and bent X-ray monochromators, neutron monochromators, and for the polarization of high-energy photons [172]. Nuclear fuel particles for high-temperature nuclear reactors are coated with less-ordered pyrolytic carbons impermeable to fission products at high operating temperatures (coated particles) [162], [343]. The carbon is deposited in a fluidized-bed, and the deposition conditions are altered so that the coating consists of several layers differing in microstructure and properties.

Since pyrolytic carbon is compatible with human tissue and has a high degree of reproducibility, it is an interesting material for bioengineering [344]. Alloyed pyrolytic carbon grades which contain a percentage of silicon are particularly useful. They are used for prosthetic heart valves, hip-joint prostheses, and dental prostheses. As mentioned above, pyrolytic carbon can be deposited in porous solids to reduce their permeability and improve the strength of the porous material [269], [270]. Fibrous materials such as carbon fabrics and carbon felts are an important infiltration substrate. The deposited pyrolytic carbon forms a closed matrix which is reinforced by the fibrous component. This composite (carbon fiber-reinforced carbon) is less sensitive to shear stresses than normal pyrolytic graphite. It is widely used in rocket nozzles, nose cones, heat shields, prostheses, and friction materials, e.g., brakes and clutches.

4.3. Graphite Compounds

4.3.1. *Surface Complexes*

Carbon and graphite form surface complexes or groups through surface reaction or chemisorption when brought in contact with certain gases and liquids [345], [346]. The proportion of these surface groups increases with rising structural disorder and surface area. This proportion is high for carbon blacks and chars and low for single graphite crystals. The total amount of gas adsorbed by graphite grades is ca. 100 – 600 mL/g. The adsorption of oxygen begins at room temperature, forming a chemisorbed surface layer. At higher temperature or in the presence of liquid oxidizing agents, functional groups such as carboxyl, phenolic hydroxyl, and carbonyl are formed. Lactones, quinoid structures, and hydroperoxides are less frequent. The highest desorption rate is achieved at temperatures between 600 and 800 °C.

Surface oxides and physically adsorbed compounds undoubtedly determine the friction properties of carbon and graphite shapes; e.g., graphite wear increases rapidly if the amount of surface “impurities” falls short of a critical threshold. On the other hand, it is still not always clear whether these surface groups have an appreciable effect on the binding strength of carbon grains or fibers distributed in a continuous binder matrix or if an increased binding strength is the consequence of interlocking or keying-in of roughened adjacent surfaces.

4.3.2. *Graphite Intercalation Compounds*

At relatively low temperatures, graphite forms intercalation compounds with numerous substances. Graphite oxide with the ideal formula $C_8O_2(OH)_2$ was the first compound investigated [347]. The following rules are valid for these intercalation compounds: 1) only highly ordered graphite or graphitizable materials yield homogeneous intercalation compounds [348]; 2) the atomic arrangement within the carbon layers is preserved; 3) the intercalated substance is regularly distributed between the carbon layers; and 4) most compounds can be reconverted into graphite.

The reagents capable of intercalation with graphite can be divided into two classes: electron donors (alkali metals, alkaline-earth metals, lanthanides, metal compounds containing hydrogen or polar molecules, and aromatic compounds) and electron acceptors (halogens, halides, oxyhalides, and acids) [349]. The number of electrons in the conduction band changes accordingly, eventually reducing the electrical resistivity considerably. Due to reagent penetration, the graphite crystal swells in the *c* direction and the identity period *I* (in nanometers) changes according to $I_{(n)} = d_i + (n - 1)0.3354$, where 0.3354 nm is the interlayer spacing of graphite, d_i is the period of a first-stage intercalation compound, and *n* is the stage number. “First-stage” compound implies, that all intervals between the carbon layers are occupied. In a second-stage compound, each intercalated layer is separated by two carbon layers, etc. (Fig. 34). A defined sublattice is attached to each stage conserving the tridimensional structure [350].

Figure 34. Graphite intercalation compounds, layer sequence (schematically) for C_7FeCl_3 (first stage) and $C_{48}K$ (fourth stage)

For the production of graphite intercalation compounds, graphite powder is heat treated in the presence of a gaseous or liquid reagent. The pressure at which intercalation begins depends on the polarity and the structural disorder of the graphite [351]. An inverse reaction of intercalation is the desorption of the intercalant. Graphite intercalation compounds have only limited stability. Compounds containing electron donors are easily oxidized when exposed to air — some are even pyrophoric — and compounds containing electron acceptors decompose easily or are strongly hygroscopic. The use of graphite intercalation compounds is, therefore, very limited. This is not true for graphite fluoride, CF_x, since this compound is adequately stabilized due to the formation of sp^3 bonds. The carbon layers do not remain flat but become rippled.

The use of graphite intercalation compounds as catalysts had already been proposed at an early time [349]. Catalysts of this type have been studied for use in the synthesis of ammonia, Fischer–Tropsch synthesis, reduction and oxidation of organic compounds, halogenation, initiation of polymerization, and hydrodesulfurization [352]. The proposed application of graphite intercalation compounds as low-resistance conductors has especially been studied with SbF_5 and $SbCl_5$ intercalants [353], [354]. At room temperature, the electrical resistivity is as low as 3×10^{-8} Ω m. The powdery material must be filled in copper tubes, the grains must be aligned parallel to the axis of the tube and the tube must be kept free from moisture. The increase in conductivity does not seem to compensate these costly operations. On a small scale, graphite fluoride is used as a lubricant [355].

4.4. Expanded Graphite and Graphite Foil Derived from Intercalation Compounds

Graphite intercalation compounds are starting materials for the production of expanded graphite particles. Intercalation compounds expand considerably during decomposition due to rapid heating. Under certain conditions, the volume increases more than 100 times [356]. Luzi observed that the expanded vermiform particles, which are segmented like the leaves of a partially opened book, are plastic and can be easily pressed into flexible sheets and other shapes [357]. The addition of a thermosetting binder to the expanded graphite particles to form bearings, seals, packings, brushes, etc. from the mixture was also proposed [358]. This process waited until about 1960, when the strong dependence of the strength of the molded product on the degree of the particle's expansion had been discovered. The expansion parallel to the *c* axis of the graphite crystal must be at least 80 times the original thickness to achieve the proper interlocking of the graphite particles necessary to form flexible graphite sheet material with sufficient strength [359].

Highly ordered graphite flakes with stack heights of at least 75 nm are used as a raw material [360]. The precursor flakes are usually treated with an oxidizing agent, e.g., mixtures of sulfuric acid and nitric acid at ca. 100 °C. After the graphite intercalation compound is formed – in this example graphite hydrogen sulfate – the particles are thoroughly rinsed with water and then rapidly heated to ca. 1000 °C. The gas pressure of the vaporized and trapped intercalants partially contributes to the exfoliation of the stacked layers. The exfoliated particles (expanded graphite) can be molded to sheets, laminates, and other useful shapes in the absence of a binder. During compression, the particles interlock and form nonrigid bonds.

Properties. The large anisotropic coefficient is due to the nearly complete alignment of the layer planes perpendicular to the compression force. Sheets are good thermal and electrical conductors parallel to the surface and semiinsulators in perpendicular planes. Graphite foils have considerable flexibility; they can, for example, be wrapped around cylinders, and they are impervious to fluids even at high temperatures. Like other graphite grades, this product is resistant to temperature, aging, and most corrosive media. Graphite foils have a smooth surface, they are under most conditions resistant to wear, and the coefficient of friction is about 0.08 – 0.1. They are not wetted by melts of glass, ceramic, or metal.

Applications. Flexible graphite is an extraordinarily good packing and sealing material, which will probably replace asbestos due to the lower health risks. Examples are cylinder-head gaskets reinforced with metallic inserts and stuffing box seals consisting of flexible graphite tapes wrapped around the shaft of a pump or valve [361], [362]. Preshaped lamellar rings are used as gaskets, e.g., for exhaust system piping. Other applications are tube linings, vessels and molds for protection against temperature and corrosive media, blackwash as protection for hot-press molds, and heat shields often in combination with carbon felt sheets. Rupture disks lined with graphite foils are workable at higher temperatures than resin-impregnated graphite disks and are more resistant to aging [363]. Heating elements can be easily cut from graphite foils and attached to high-temperature furnaces [364].

5. Activated Carbon

Klaus-Dirk Henning and Hartmut von Kienle

5.1. General Aspects

Definition. Activated carbon [7440-44-0] is the collective name for carbonaceous adsorbents which are defined as follows [365]: Activated carbons are nonhazardous, processed carbonaceous materials having a porous structure and a large internal surface area. They can adsorb a wide variety of substances, that is, they are able to attract molecules to their internal surface and therefore act as adsorbents. The pore volume of activated carbons is generally greater than 0.2 mL/g. The

internal surface area is generally greater than 400 m^2/g. The width of the pores ranges from 0.3 to several thousand nanometers.

All activated carbons [366-370] are characterized by a ramified pore system (Fig. 35) in which pores of various sizes, such as mesopores (d = 2 – 50 nm), micropores (d = 0.8 – 2.0 nm) and submicropores ($d \leq$ 0.8 nm) branch off from macropores ($d \geq$ 50 nm).

Figure 35. Schematic model of activated carbon

X-ray investigations show that the carbon is mainly in the form of very small crystallites with a graphite structure. However, the typical graphite arrangement of the carbon platelets one above the other is absent. The crystalline regions are only 0.7 – 1.1 nm thick and 2.0 – 2.5 nm in diameter, a considerably smaller size than is observed in graphite (see Table 12).

Table 12. Typical dimensions of crystal regions

	L_a, nm	L_b, nm	$c/2$, nm
Natural graphite	210	94	0.351
Activated carbon	2.0 – 2.5	0.7 – 1.1	0.35 – 0.37

This means that in each crystallite there are usually only three or four layers of carbon atoms with about 20 – 30 carbon hexagons in each layer. The spaces between the crystallites are filled with amorphous carbon which is bonded in three dimensions with other atoms, especially oxygen. The irregular arrangement of the carbon atoms is broken up by numerous cracks and fissures (pores), which are often idealized as cylindrical in shape. The large number of very fine pores (micropores and submicropores) gives activated carbon a large inner surface, which is the basis of its remarkable adsorption properties.

A common feature of these adsorbents is an amorphous structure with a high carbon content and a hydrophobic surface properties. Activated carbon is made on commercial scale from carbon-containing raw materials (wood, peat, coconut shells, lignite, hard coal) by chemical activation or gas activation. Activated carbon is commercially available in shaped (cylindrical pellets), granular, or powdered form.

History. The medical use of charcoal was described as early as 1550 B.C. in an ancient Egyptian papyrus and later by HIPPOCRATES and PLINY THE ELDER. The products described at that time and later in the 1700s were of varying effectiveness and included wood, blood, and animal charcoals.

The decolorization of sugar solutions by bone black was first carried out commercially in England in 1811. Bone black, however, consists mainly of calcium phosphate and contains only a small amount of carbon. Strictly speaking, it is not a carbon. Methods of obtaining decolorizing charcoals from plant materials were first set out in British patents in 1856 – 1863. The first industrially manufactured activated carbons in the proper sense were Eponit decolorizing carbons, which have been produced since 1909 according to a patent of R. VON OSTREJKO [371] by heating wood charcoal with steam and carbon dioxide in a furnace specifically designed for the purpose.

In 1911 in the Netherlands, Norit NV began commercial activation of peat by using steam. The chemical activation of sawdust with zinc chloride to produce Carboraffin was first described in a patent of the Austrian Association for Chemical and Metallurgical Production [372]. This process was first operated in Aussig, Czech Republic, and in 1915 by Bayer. In the United States during World War I, the activation of coconut charcoal for gas masks was developed. The many and varied applications of activated carbon are amply illustrated by the existence of over 1500 manufacturing patents worldwide [367].

During the first decades of this century, activated carbon was used mainly for the purification of products of the chemical, pharmaceutical, and food industries; purification of drinking water was also an important application from the outset. It is increasingly used for the prevention of environmental pollution and for meeting the constantly increasing demands for purity of natural and synthetic products.

5.2. Carbonaceous Adsorbents

5.2.1. *Types of Carbonaceous Adsorbents*

Due to the wide variation in the properties of activated carbon there is no comprehensive nomenclature or standardization. The product group can be characterized by appearance, pore radius distribution, or by typical applications.

Classification by *appearance*:

- Powdered activated carbon (PAC)
- Granular activated carbon (GAC)
- Cylindrical pellets
- Spherical pellets

- Activated carbon fibers (ACF)
- Activated coke

Classification by *pore radius distribution*:
- Activated coke
- Activated carbon
  - fine-pore
  - medium-pore
  - wide-pore
- Carbon molecular sieves (CMS)

Classification by *field of application*:
- Carbon molecular sieve (CMS)
- Decolorizing carbon
- Water-treatment carbon
- Catalyst carbon
- Drinking-water carbon
- Solvent-recovery carbon

Carbonaceous adsorbents are usually characterized by appearance as powder, granules, or formed shapes such as cylindrical or spherical pellets. Grouping only according to end use is not meaningful because the requirements are so varied. Also no useful classification is possible on the basis of raw materials or production methods. In practice these products are often called, for example, powdered decolorizing carbon, granular carbon for water treatment, or pelletized catalyst carbon.

In industrial practice, carbonaceous adsorbents are often classified by their pore radius distributions into activated carbon, activated coke, and carbon molecular sieves [373]. Some information on characteristic data and applications of commercial activated cokes and carbon molecular sieves are given in Tables 13, 14, and 15.

Table 13. Gas-phase applications and typical data of carbon-based adsorbents

Adsorbent	Activated carbon, fine-pore	Activated carbon, medium-pore	Activated carbon, wide-pore	Activated coke	Carbon molecular sieves
Typical applications	intake air and exhaust air cleanup, odor control, adsorption of low-boiling hydrocarbons	solvent recovery, adsorption of medium-boiling hydrocarbons	adsorption and recovery of high-boiling hydrocarbons	dioxin and furan adsorption, SO_2 and NO_x removal	N_2 and O_2 recovery from air, CH_4 from biogas

Figure 36 shows the schematic pore diameter distribution of activated carbon, activated coke, and carbon molecular sieves. Carbon molecular sieve clearly exhibits narrower pores than activated carbon and activated coke. The pore diameters are matched to the molecular sizes of the gases to be adsorbed.

Figure 36. Schematic pore diameter distributions of carbonaceous adsorbents

Activated carbon typically exhibits pore volumes of well above 25 cm^3/100 g and pore diameters of less than 2 nm. The specific inner surface area of commercial activated carbons ranges between 500 m^2/g and 1500 m^2/g. Due to its hydrophobic character, activated carbon is particularly suited to the adsorption of nonpolar organic substances, which has led to a broad range of applications in air pollution control and water treatment. In addition, catalytic reactions occur on activated carbon surfaces. For this reason activated carbon is used commercially as catalyst or catalyst support.

Activated coke is manufactured from lignite or hard coal and has typical pore volumes of up to 25 cm^3/100 g and specific surface areas of up to 400 m^2/g. Depending on the source material and the manufacturing process, adsorptive or catalytic characteristics may predominate. Activated coke is used for removing SO_2 and dioxins from waste and flue gases.

Carbon molecular sieves have micropore diameters that range from 0.50 to 1.00 nm with pore volumes of up to 20 cm^3 /100 g. The separation effect of carbon molecular sieves (CMS) is based on differing rates of diffusion into the pore system. For this purpose the pore diameters of the CMS are matched carefully to the diameters of the molecules to be separated. Thus, a kinetic separation effect (sieve effect) is obtained. Larger molecules are adsorbed at a substantially lower rate in spite of higher equilibrium loads. For example, oxygen is adsorbed ten times faster than nitrogen although its molecular diameter is only slightly smaller.

5.2.2. *Chemical Properties*

Activated carbon contains not only carbon, but also small amounts of oxygen, nitrogen, sulfur and hydrogen, which are chemically bonded in the form of various functional groups, such as carbonyl, carboxyl, phenol, lactone, quinone, and ether groups [370], [374], [375]. These surface oxides are sometimes derived from the raw material or they can be formed during or after the activation process by the action of air or water vapor. They usually have acidic character (seldom basic), and they give to the activated carbon the character of a solid acid or base. Under suitable conditions, surface sulfides and carbon – chlorine compounds can be formed. These surface chemical properties play a significant role in adsorption and catalysis.

All the raw materials used for the production of activated carbons contain mineral components which become concentrated during the activation process. Moreover, the inorganic chemicals used in chemical activation are often only incompletely removed. The ash content of many products is reduced by water or acid washing. Hence, commercial products contain from a few tenths of a percent up to 20 % ash. The main constituents of the ash are salts of the alkali and alkaline earth metals, mostly carbonates and phosphates, together with silica, iron, and aluminum oxides.

5.2.3. *Mechanical Properties*

Performance characteristics for activated carbon are generally expressed in relation to its mass. If figures on a volume basis are needed, bulk density or tapped density figures are also needed to carry out the conversion calculation.

The bulk density is very much dependent on the filling technique, the geometry of the vessel used, and the grain size of the material. Therefore, a defined tapping or shaking process is usually included in the case of the higher tapped densities [365].

Another important feature of activated carbon is its grain size distribution. This determines the resistance of a layer of activated carbon to the flow of a liquid or gas (Fig. 37).

Figure 37. Pressure drop of molded activated carbon with different particle diameter (20 °C, 1-m layer, dense packing)

The fineness of grinding of a powdered carbon affects the filtration properties.

For filling a high adsorption tower or for any other static loading, the granules or pellets must be resistant to crushing. For transportation procedures such as pneumatic delivery, the abrasion resistance is very important. Care must also be taken that the thermal and chemical resistance properties are adequate to withstand any severe temperature variations or aggressive environments such as oxidizing atmospheres.

5.2.4. *Adsorption Properties*

The adsorption properties of activated carbon [366-370], [376-380] depend principally on its inner surface area, which in commercial products is 500 – 1500 m^2/g. To make use of the inner surface which is provided by the walls of the pores, the accessibility of this surface is important, that is, the pore size and the pore size distribution. This is determined by various methods, mostly from nitrogen adsorption isotherms, and is represented as integral or differential distribution curves (Fig. 38).

Figure 38. Pore size distribution of different activated carbons

—— Gas-phase activated carbon (narrow pores); · · · · · Liquid-phase activated carbon (wide pores)

The term “adsorption“ refers to the accumulation of gaseous or dissolved components on the surface layer of a solid (the adsorbent) [373], [375-379]. On their surface activated carbons have “active sites“ where the binding forces between the neighboring carbon atoms are not fully saturated and adsorption of foreign molecules takes place. Depending on the intensity of interactions between adsorbent and the component to be adsorbed, an adsorption enthalpy of 5 – 65 kJ/mol is released. With increasing temperature the quantity of the matter adsorbed in the equilibrium state decreases; in gas phase the influence of temperature on adsorption capacity is greater than in liquid phase. The reverse of the adsorption process is called desorption.

The adsorption mechanisms are classified as chemisorption and physisorption. Physisorption is reversible and involves only physical interaction forces (van der Waals forces). Chemisorption is characterized by higher interaction energies which result in a chemical modification of the adsorbed component.

The adsorption capacity (loading) of an adsorbent for a given component is normally represented as a function of the component's concentration c in the gas (or liquid) for the equilibrium condition at constant temperature, known as the adsorption isotherm $x = f(c)T$.

There are a variety of approaches derived from different model assumptions for the quantitative description of adsorption isotherms (see also ⟶ Adsorption – Thermodynamics, Equilibria, and Heat of Adsorption, ⟶ Air). The Langmuir isotherm is based on the assumption of ideal monolayer adsorption. The BET isotherm additionally takes into account multilayer adsorption. However, their underlying assumption of a homogeneous surface structure is not applicable to adsorbents whose structure is characterized by active sites with widely differing bonding energies. In such cases, the empirical Freundlich isotherm is often useful. According to the Freundlich isotherm, the logarithmic adsorbent loading increases linearly with the partial pressure of the component to be adsorbed in the carrier gas.

However, commercial adsorbents do not have a smooth surface but are highly porous solids with a very irregular and rugged inner surface. This fact is taken into account by the potential theory which forms the basis of the Dubinin isotherm. It describes the logarithm of the adsorpt volume V, which is determined via the density of the liquid phase of the component to be adsorbed as a function of the relative saturation $(\log p/p_s)^n$. According to [376], [377], this equation is applicable to some wide-pore activated carbons with an exponent of $n = 1$, while an exponent of $n = 2$ results for a variety of activated carbons with organic vapors and certain carbon molecular sieves.

At adsorption temperatures below the critical temperature of the component to be adsorbed, the adsorbent pores may fill up with liquid adsorpt. This phenomenon is known as capillary condensation and enhances the adsorption capacity of the adsorbent. Assuming cylindrical pores, capillary condensation can be quantitatively described with the aid of the Kelvin equation, the degree of pore filling being inversely proportional to the pore radius.

In the liquid phase, the empirical Freundlich isotherm is a very helpful tool, as the position and gradient of this isotherm allows conclusions to be drawn regarding carbon properties in practical applications. Often, specific substances like phenol, iodine, alkylbenzenesulfonate, or methylene blue are used for characterizing the adsorptive properties of activated carbons.

For commercial adsorption processes not only the equilibrium value, but also the rate at which it is achieved (adsorption kinetics) is of decisive importance. The adsorption kinetics are determined by the following series of individual steps:

- Transfer of molecules to the external surface of the adsorbent
- Boundary layer film diffusion
- Diffusion into the particle
- Actual adsorption step

Adsorption kinetics in the liquid phase are much slower than in gas phase; therefore adsorber design is different for liquid and gas phase applications (see Table 16).

Table 16. Typical design data of adsorbers for adsorptive gas and water purification

Parameter	Gas purification	Water purification
Carbon particle size, mm	3 – 5	0.5 – 2.5
Depth of adsorbent bed, m	0.5 – 1.5	2 – 15
Mass transfer zone, m	0.05 – 0.3	0.5 – 5
Superficial velocity, cm/s	10 – 50	0.03 – 0.4 *
Residence time, s	1 – 15	1800 – 7200 **

*1 – 15 m/h.
**0.5 – 2 h.

5.2.5. *Quality Control*

Methods of quality control are of great importance for both technical and commercial practice. Some tests are used in production control to check the basic properties of final or intermediate products. Special requirements are placed on acceptance tests, since they may be used in disputes between buyer and supplier. The buyer wishes to be certain of the material's suitability for his purpose and uses tests in which the conditions simulate as closely as possible his operational conditions. For example, active carbon for sugar refineries is tested for its decolorizing efficiency on a molasses solution to

determine the adsorption properties but also side effects due to the ash content and pH value. A gas-mask carbon is tested dynamically for its service time with the substances that are to be removed in practice [365], [368].

Physical and Mechanical Tests [365]. *Bulk density* (DIN-ISO 787 11, ASTM D2854) is defined as the mass of a unit volume of the sample in air, including both the pore system and the voids between the particles. It is expressed in kg/m^3 on a dry basis. The bulk density of activated carbon depends on the shape, size, and density of the individual particles. Bulk density data are useful for the estimation of tank or packing volume.

The *particle density*, otherwise known as Hg density, is defined as the mass of a unit volume of the carbon particle, including its pore system, normally expressed in g/cm^3. The particle density is an important characteristic of granular carbon that is used for the determination of bed porosity or void fraction. This in turn, is necessary for the determination of numerous other properties. Under the conditions of this method, pores $r \geq 7$ µm or more in radius are filled and therefore do not contribute to the density of the particle.

The *absolute* or *helium density* is defined as the mass of a unit volume of the solid carbon skeleton that is inaccessible to He, normally expressed in g/cm^3.

The *pressure drop* gives information about the resistance to flow of a gas through a pelleted or granular carbon layer. The pressure drop over a packed bed is adequately defined by a modified form of the semi-empirical Ergun equation as a function of the shape and size of the particles and the temperature, pressure, and superficial velocity of the gas. It is expressed in pascals per meter of carbon bed length. Air is passed through an activated carbon layer of given length, and the pressure drop is measured as a function of gas velocity. The resistance to the flow of liquids or gases has a practical significance, since it is related to the filtration resistance of a carbon layer. The relationship between flow rate and pressure drop is shown in Figure 37.

Particle size is an important property that influences the flow characteristics, adsorption kinetics and catalytic behavior of granular activated carbon layers. The grain size distribution of granular activated carbons (ASTM D2862) is determined by using standard sieves and motor-driven sieving apparatus. All common methods provide for mechanical separation with standard sieves, the aperture of which is expressed in millimeters or mesh. Determination of particle size by sieving is not applicable to extruded activated carbons. The fineness of powdered carbons can be determined by elutriation or by laser-beam scattering. Equipment such as the Coulter counter or sedimentation tests lead to incorrect results because the individual particles of activated carbon vary in electrical conductivity and density.

Mechanical strength is an important factor in most technical applications of granular activated carbon. Mechanical strength tests are modified to conform with the technical requirements: it differs for active carbon for gas masks, in which the granules suffer attrition, from that for solvent recovery, for which coherence of the granules is critical. The determination of mechanical strength simulates the resistance to abrasion or attrition under practical conditions. Depending on various practical requirements, there are many different test methods using vibration, impact, rotary motion, or motion as in a fluidized bed. A variety of tests are available for the evaluation of the mechanical strength of granular activated carbon. In these tests the change in particle size distribution or the amount of fines produced is determined. An overview of the wide range of hardness tests, which test different aspects of the mechanical strength and hence cannot be related to one another mathematically is given in the following:

Ball-mill hardness:	The activated carbon is abraded for a given time in a horizontal cylinder with steel or ceramic balls under prescribed conditions
Abrasion strength:	The activated carbon is abraded by an iron rod in a horizontal rotating cylindrical sieve of given dimensions for a prescribed time
Impact hardness:	The activated carbon particles are broken by dropping a weight onto a sample under controlled conditions
Ball-pan hardness (ASTM D 3802):	The activated carbon is shaken for a given time in a pan together with a given number of steel balls of known diameter
Crushing strength:	The pressure required to crush a granule of activated carbon (not applicable for broken granules)
Impact hardness (fluidized bed):	The activated carbon is pneumatically agitated for a standard time in a vertical cylinder, the top of which is equipped with an impact plate.
Attrition and abrasion resistance (ASTM D4058):	The activated carbon is rotated for a period of time in a cylindrical drum having a single baffle
Stirring abrasion (AWWA B604):	The activated carbon is abraded by a T-shaped stirrer in a special abrasion unit
Ro-Tap abrasion (AWWA B604):	The activated carbon is shaken with steel balls in the testing pan of a Ro-Tap sieve machine

Chemical and Physicochemical Tests. *Moisture content* (ASTM D2867) is determined by heating the sample in air in an oven at constant temperature to constant weight (3 h at 150 °C). The oven-drying method is used when water is the only volatile material present in the activated carbon. A xylene distillation method is used when the carbon is known or suspected to be heat-sensitive or to contain water-insoluble volatile compounds as well as water.

Ash content (ASTM D2866) is determined by ignition of the sample to constant weight in a muffle furnace (air circulation) at 650 ± 25 °C. Frequently only the water-soluble or acid-soluble part of the ash is determined. In cases where certain cations or anions have an adverse effect on the products, they can be determined by first extracting with hydrochloric acid, nitric

acid, or water in a prescribed way, and then analyzing the extract. Arsenic, cyanide, and sulfide must be determined on the activated carbon itself.

Volatile matter is determined by heating the sample at 900 °C for 7 min. The percentage of volatile matter is calculated from the weight loss of the sample, corrected for moisture content.

Ignition temperature (ASTM D3466) is determined by exposing a sample of carbon to a heated air stream, the temperature of which is slowly increased until the carbon ignites. The temperature of the carbon bed and of the air entering the bed are recorded, and ignition is defined as the point at which the carbon temperature suddenly rises above the temperature of the air entering the bed. The test provides a basis for comparing the ignition characteristics of different carbons, or the change in ignition characteristics of the same carbon after a period of service.

The *self-ignition test* (IMDG Code, Class 4.2) determines whether a sample of chemically activated carbon ignites at 140 °C under specified conditions. Steam-activated carbon is considered to be non-self-ignitable.

Activated carbon bearing inorganic and chemically active groups on its surface may alter the pH of liquids to which it is added. A predictive standard test giving, a good approximation of actual conditions has been devised. The acid or alkali content is determined by boiling an aqueous suspension and measuring the pH of the filtered or decanted aqueous extract. The pH of the extract is defined as the *pH value* of the activated carbon.

Adsorption Measurements. The most common method of measuring adsorption properties of activated carbon is by the determination of the BET surface, e.g., according to DIN 66 131. However, the numerical value thus obtained has only a limited practical significance, because in a practical situation, the molecules adsorbed are usually to large to reach the inner surface of the very small pores due to the large size of their molecules, whereas determination of the nitrogen isotherm [381] or assessment of porosity by using mercury vapor [382] gives deep penetration into the pore structure. It is easier to estimate the porosity by measuring the amount of benzene or cyclohexane vapor adsorbed by activated carbon at 20 °C and at a range of partial pressures. The difference between two measured values of the isotherm represents a certain pore volume, and limiting values of pore sizes can be related to this. An example of the single-point method is the determination of the carbon tetrachloride retentivity according to ASTM [383].

Carbons for gas masks are characterized by the breakthrough times (holding times or service times), which are determined by using certain test substances such as chloropicrin.

For many practical applications involving gas-phase adsorption, the total adsorption capacity is of minor interest in comparison with the adsorption capacity after regeneration. In such cases, the “working capacity” after several cycles of adsorption and desorption is quoted.

5.3. Production

5.3.1. *General Aspects*

Nearly all carbon-containing materials can be used for the manufacture of activated carbon; e.g., wood, nut shells, fruit stones, peat, charcoal, brown coal, lignite, bituminous coal, mineral oil products, and some waste materials. Cellulose and organic polymers are used for the manufacture of fiber and spherical activated carbon [366-370]. These starting materials vary considerably with regard to the extent to which they can be activated; e.g., calcined petroleum coke or high-temperature coke from coal are difficult materials, while wood charcoal is easily activated. In addition, the purity of the activated carbon produced as well as its pore size distribution is very much dependent on the starting material.

There are two principal methods of activation, i.e., that which uses chemicals and that which uses gases. *Chemical activation* is based on the dehydrating action of certain substances, e.g., phosphoric acid [7664-38-2] or zinc chloride [7646-85-7], mostly on uncarbonized starting materials such as sawdust or peat. A temperature of 400 – 1000 °C is usually used. After removal of the chemicals, e.g., by extraction, the porous and active carbon structure of the raw material remains. Cellulose fibers or woven materials produce products having the same physical form, but made of activated carbon. Polyacrylonitrile fibers are also used.

Gas activation entails the use of gases containing combined oxygen, such as steam or carbon dioxide. At temperatures of 800 – 1000 °C, some of the carbonaceous starting material is decomposed, producing numerous extremely fine pores or cracks. The inner surface area of the carbon determines its degree of activation. The yield is, therefore, dependent on the degree of activation. A high degree of activation is associated with a low yield, and this can be between 20 and 60 %.

Production of activated carbon can be carried out in rotary kilns, multiple hearth furnaces, or furnaces of the vertical-shaft or fluidized-bed type, each type being suitable for a particular particle size of starting material. At the present time, internally heated rotary kilns are most commonly used, since these are suitable for production of activated carbon of a large range of particle sizes from powder and granular material up to cylindrical pellets. The activation of coarse materials such as softwood and beech wood charcoal is carried out in a shaft furnace. The product is usually ground to a powder for use as a decolorizing agent. Fluidized-bed furnaces are suitable for granules and cylindrical pellets.

Important factors that determine the adsorption properties of an activated carbon are the pore volume, the pore size distribution, and the type of functional groups on the surface (surface oxides). The large inner surface area is mainly due to the micropores. Consequently, particular attention is paid to these during manufacture. Pore volume and pore size are affected by the type of starting material and the heating process. Thus, gas activation of coconut shell charcoal always gives a high proportion of fine pores, while the same process with softwood charcoal yields a product with open pores. Chemical activation produces carbons with extremely high proportions of meso- and micropores.

5.3.2. *Raw Materials*

Wood, sawdust, peat, straw, and other cellulose-containing materials are usually only treated by chemical activation.

The direct gas activation of uncarbonized products is possible, although usually with these raw materials, a carbonization process (possibly at low temperature) is added. This has the advantage that the partly carbonized intermediate product can be screened, giving a standard particle size. Norit NV (Netherlands) carries out gas activation of peat without producing any partially carbonized intermediate material. In a further development of the classical procedure of OSTREJKO [371], activated carbon is produced directly from uncarbonized carbonaceous material by heating to 840 – 900 °C in an atmosphere of combustion products that contains hydrocarbons but no oxygen [372].

Raw materials very suitable for gas activation are wood charcoal, nut shell charcoal, and coke from brown coal or peat. *Wood charcoal* [7440-44-0] is obtained by carbonization of pieces of wood from beech, spruce, or pine in large-capacity batch retorts or continuous vertical retorts (⟶ Charcoal). Carbonized coconut shells are used by many producers in Europe, Japan, and the Far East.

Bituminous coals are suitable for gas activation to varying extents. A useful criterion is their carbon, oxygen, and hydrogen contents. The diagram in Fig. 39 gives an approximate guide to these values [384]. The high-carbon materials graphite and anthracite are very difficult to activate. Bituminous coals with high oxygen and hydrogen contents can have troublesome sticking and swelling properties. In these cases, a preoxidation is usually carried out before gas activation [385], [386]. This is done with air or oxygen-containing gases at temperatures between 150 and 350 °C. This causes 5 – 30 % oxygen to be taken up. The optimum temperature is 220 – 250 °C. This procedure is carried out as long as necessary to cause complete disappearance of the swelling and sticking properties; as much as 5 h may be required.

Figure 39. Characterization of different raw materials

Bituminous coal may be more easily activated after addition of mineral acids such as phosphoric acid. For this purpose, the raw material is finely ground and mixed with a few percent of acid before being formed into shapes. This process, which was developed by Carborundum [387], is operated in the United States by Ceca. It uses a combination of chemical and gas activation. In some types of bituminous coal, the quality of the activated product is adversely affected by the high ash content; however, a small ash content that includes potassium compounds, for example, can have a catalytic effect and, when the material is preoxidized, can lead to intensive gasification of the coal. In these cases the ash content of the raw material can be reduced by grinding and flotation. The preoxidation can be carried out on the powder or after granulation. Some companies which activate bituminous coal: the Calgon Carbon Corp. (United States), Norit (United States), and the CarboTech Aktivkohlen GmbH (Germany).

Brown coals and the related lignites offer an inexpensive and readily activated starting material for the production of activated carbons. Their relatively high ash and sulfur contents are detrimental. Therefore, methods have been developed for removing ash from brown coal before coking, e.g., by treatment with an oil – water mixture. The ash goes into the aqueous phase, while the coal remains in the oil phase. By this means the ash content can be reduced by 80 – 90 %. Lignite is activated in high tonnages by Norit in the United States according to a process developed by ICI United States [388].

Many publications and patents describe the production of activated carbon from *mineral oil products*. Petroleum sludges, fly ash, old tires, domestic refuse, and sewage sludge have also been proposed as raw materials for activated carbon, but none of these products have attained commercial importance [389], [390]

5.3.3. *Activating Furnaces*

Shaft furnaces originally consisted of simple vertical chambers with smooth walls made of refractory bricks. Heating is external. As the process was developed, the mixing of the feed materials was improved and, consequently, so was the reaction with the activating gas. This was done by installing ceramic attachments in the form of gratings or replaceable louvers which can control the direction and velocity of the gas stream within the furnace. The reaction gases (hydrogen and carbon monoxide) can be removed at various levels. The temperature of the furnace, usually 5 – 8 m high, can be controlled by means of a number of burners or afterburners (Fig. 40) [391]. Shaft furnaces can be used for the reactivation of exhausted activated carbon [392].

Figure 40. Shaft furnace

Rotary kilns are the most commonly used activating furnaces. Due to the length of the kiln and the high temperatures necessary for gas activation, direct heating is the only feasible method when the materials of construction of the kiln are

considered. To be able to control gas composition and temperature throughout the entire length of the kiln, several burners and gas supply lines are distributed along and around the kiln casing, e.g., in the American Norit furnace. Figure 41 shows an arrangement including lifters to give improved mixing of the feed material. By means of a variable steam injection rate, the water vapor content and, therefore, the activation rate can be further controlled.

Figure 41. Rotary kiln for steam-activation process

a) Steam; b) Gas; c) Air; d) Burner; e) Brick lining; f) Lifters

Multiple-hearth furnaces (Fig. 42) with rotating arms and stationary floors on each stage are used by several firms such as Calgon in the United States and Belgium. This type of furnace is also operated for the purpose of reactivation, e.g., by Windhoek Municipality (Republic of South-West Africa).

Figure 42. Multiple hearth furnace

a) Raw material silo; b) Inlet; c) Burner; d) Off-gas suction; e) Outlet for activated carbon; f) Dust collector; g) Off-gas stack

Fluidized-bed furnaces offer the advantage of extremely intensive heat and mass transfer. This means not only that the activating gases are quickly brought into contact with the raw material, but also that the waste gases are just as quickly removed. Furnaces have been developed which are operated continuously (Fig. 43) and in which several fluidized beds are run in series. The activating gases may be introduced into the spaces between the fluidized layers and also into the circulatory system. Thus, it is possible to achieve a preoxidation in the first stage with oxygen-containing gas and then to carry out the actual activation with oxygen-free gases in a second stage. The activation in the fluidized bed is so intensive that usually only fragile products with poor resistance to abrasion are obtained, which are processed to give decolorizing carbon in powder form. By maintaining certain conditions, in particular by keeping the water vapor content of the gas below 0.6 kg/m^3 and by maintaining a neutral or slightly reducing atmosphere, it is possible to produce abrasion-resistant granules.

5.3.4. *Methods of Activation*

5.3.4.1. *Chemical Activation*

Zinc Chloride Process. In the classical zinc chloride process for the chemical activation of carbonaceous materials, 0.4 – 5.0 parts of zinc chloride as a concentrated solution are mixed with 1 part peat or sawdust. The mixture is then dried and heated to 600 – 700 °C in a rotary kiln. The product is washed with acid and water, and the zinc salts are recovered. In some cases, chemical activation is followed by steam activation to obtain additional fine pores. In spite of the efficiency and simplicity of the process, it is in decline because of the problems of environmental contamination with zinc compounds.

Phosphoric acid [7664-38-2] can be used to treat either uncarbonized or carbonized raw materials, and the process is operated by Ceca (France), Hooker (Mexico), and Norit (United Kingdom and United States). Finely ground raw material such as sawdust is mixed with a phosphoric acid solution, forming a pulp. This is dried and heated to 400 – 600 °C in a furnace such as a rotary kiln. The phosphoric acid is then extracted, sometimes after neutralizing it to give phosphate salts, and the material is dried, giving an activated carbon which usually has finer pores than the zinc chloride product. Activation with a combination of phosphoric acid and steam is also possible.

As with zinc chloride activation, a highly active decolorizing carbon is obtained by a rapid process in high yield and at a relatively low reaction temperature. However, the cost of recovering the activating chemicals is high. Activation by phosphoric acid has become more popular and there is no doubt that improved methods of phosphoric acid recovery have contributed to this. These innovations have hardly been reported in the literature; the know-how is not divulged by the producers.

Other Chemicals. In the literature, many chemicals have been proposed for the activation of carbonaceous raw materials, but none of them attained industrial importance.

5.3.4.2. *Gas Activation*

In gas activation, carbonaceous material is treated at elevated temperatures with suitable gases, the most common being steam, carbon dioxide, and mixtures thereof. Experiments using graphite have established the reaction velocities: steam has

been shown to be 8 times as reactive as carbon dioxide. Both gases behave as mild oxidizing agents at 800 – 1000 °C, there being several simultaneous reactions:

$$H_2O + C \rightarrow CO + H_2 \quad \Delta H = +117\ \mathrm{kJ}$$

$$2H_2O + C \rightarrow CO_2 + 2H_2 \quad \Delta H = +75\ \mathrm{kJ}$$

$$CO_2 + C \rightarrow 2\,CO \quad \Delta H = +159\ \mathrm{kJ}$$

Due to the endothermic character of these reactions, the carbon particles must be brought into intimate contact with the activating gas. This must be hotter than the required reaction temperature; otherwise, the necessary heat energy will not be provided, or only with difficulty. Below 800 °C, the reaction velocity is so seriously reduced that the activation process ceases for all practical purposes. A useful improvement to the heat supply can be obtained by combustion of gases produced during activation:

$$CO + 0.5\,O_2 \rightarrow CO_2 \quad \Delta H = -285\ \mathrm{kJ}$$

$$H_2 + 0.5\,O_2 \rightarrow H_2O \quad \Delta H = -238\ \mathrm{kJ}$$

Modern furnace construction takes advantage of this fact by introducing oxygen and air at suitable points, which at the same time has the effect of regenerating the activating gases. Thus, the best way of dealing with the carbon monoxide and hydrogen that are produced is by burning them off in the reactor itself. This is necessary for the additional reason that these gases reduce the velocity of activation, carbon monoxide to a noticeable extent and hydrogen very markedly. The reaction mechanism for the gas activation of carbon with steam or carbon dioxide is characterized by an initial adsorption of these gases with subsequent oxidation of the carbon surface as the rate-determining step:

$$C + CO_2 \rightarrow C(O) + CO$$

$$C(O) \rightarrow CO$$

where C(O) signifies surface oxide.

The retarding action of the carbon monoxide and hydrogen can be attributed to the formation of C(CO) and C(H) surface complexes, the latter in particular being much more stable than the C(O) surface complex. Thus, the active sites which could adsorb oxygen are blocked by hydrogen.

Oxygen or air are unsuitable as activating gases. In a mixture with steam or inert gas, small amounts of oxygen lead to activated material with very large pores. Oxygen reacts with carbon about 100 times as fast as carbon dioxide. This reaction velocity is even further increased by potassium salts, so that potassium-containing raw materials react so vigorously when oxygen is present in the gas that an uncontrolled combustion takes place without producing activation. The chemical condition of the carbon surface, especially the presence of larger or smaller amounts of carbonyl and carboxyl groups, can determine the adsorption properties of the activated carbon and, very importantly, its properties as a catalyst.

Acidic surface oxides are formed by heating activated carbon in air or oxygen for a short period below the ignition temperature. If carbon is first heated to 1000 °C and then allowed to react with air at room temperature, basic surface oxide groups are formed, although the quantity of these is at most much less than the quantity of acidic groups.

It has long been known that the gas activation of carbonaceous materials is accelerated by small amounts of various compounds, e.g., salts of alkali and alkaline earth metals, almost all chlorides, sulfates, acetates, and carbonates, as well as most acids and hydroxides. The most important catalysts used industrially are caustic potash and potassium carbonate. Amounts between 0.1 % and 5 % are used. The activation accelerators can be used in solid form mixed with the finely powdered carbonaceous substances or added as solutions, sometimes followed by molding into shapes and low-temperature carbonization.

If bituminous coal is activated with addition of alkali metal salts, the gas mixtures containing carbon dioxide must be used for the activation process in preference to pure steam.

In addition to these accelerators, the patent literature also refers to compounds of iron, manganese, and aluminum.

The theory of catalytically accelerated activation is described in [394] and [395].

5.3.5. *Granular and Pelletized Carbons*

For a number of applications in liquid and gas purification, the activated carbon must be provided in the form of grains or granules; therefore, the raw material used to produce it must be similarly shaped, e.g., wood charcoal or coconut shell charcoal. Alternatively, the raw material, such as coal, can be pulverized, briquetted by using a binder, and finally carbonized. Before activation, the material is broken down to the required particle size. For applications requiring a carbon with a high mechanical strength, it is often an advantage to use carbon which has been specially preshaped, i.e., pelletized. In some cases, the hardness is dependent not only on the raw material and binder, but also on the degree of activation and porosity. Highly activated carbons have a high pore volume and, therefore, low density and strength. Similarly, products with open pores are not as hard as those with fine pores.

Carbons in pellet form are produced from finely powdered raw material as follows. The powder is first mixed with a binder in a heated paste mixer to give a flowable mass. This material is then extruded to form strands ≥ 1 mm in cross section, or may be formed discontinuously in a cylinder press (Fig. 44). These strands, sometimes after drying, are then broken into short

lengths, the length of each piece being approximately equal to its diameter. These are then either chemically activated or carbonized at 400 – 500 °C and finally gas-activated. Suitable binders are coal tar, wood tar, lignosulfonic acids, or mixtures of phenols and aldehydes or their condensation products. Bases such as caustic soda or chalk neutralize the acidic groups of the tar and improve gas activation.

Figure 44. Flow sheet for production of pelletized activated carbon

a) Crusher; b) Mill; c) Kneader; d) Extrusion; e) Drying; f) Carbonization; g) Activation; h) Screening; i) Packing

A simplified flow sheet of the CarboTech process is shown in Figure 45. The specially de-ashed hard coal feed is finely ground, and partially oxidized with air. Then the coal dust is mixed with a binder. The binder is added to produce a plastic coal/binder mixture that can be used to form shaped extrudates of the desired diameter. The extrudates are then carbonized to activated coke in a rotary kiln at 900 – 1000 °C. In a final activation step, the carbon skeleton of the activated coke is partially gasified by steam activation in a multistage fluidized-bed furnace.

Figure 45. Production steps of formed activated carbon

The production of pelletized activated carbon from material which is already in an activated state, such as powdered decolorizing carbon, is at the present time of little commercial importance. In the beverage and food industries, products of this type have found increased application due to their dust-free nature. To make the fullest use of the available adsorption capacity of agglomerates of this type in an aqueous medium, it is necessary to disintegrate them.

There are a number of patents describing the production of microporous carbon spheres from pitch. The process involves several stages: melting, dispersing, oxidizing with air to render the material insoluble, and finally, activation by steam.

5.3.6. *Carbon Molecular Sieves*

Carbon molecular sieves for air separation are produced from coal, coconut shells, or resins. For example, bituminous coal is ground to a fine dust and oxidized in air at a temperature below the ignition temperature. The oxidized coal is mixed with a binder and shaped into pellets with diameter of 2.5 mm. The pellets are carbonized in a special rotary kiln.

The final step is treatment with hydrocarbon under cracking conditions to deposit carbon exactly on pore openings [396]. The pore diameter is then smaller than that of the initial material, and the diameter of the “bottle necks“ are on the same range as those of nitrogen and oxygen molecules. Oxygen molecules can penetrate much quicker than the nitrogen molecule into the pores. Therefore, the most of the nitrogen is recovered, while almost all of the oxygen is adsorbed.

5.3.7. *Further Treatment*

Many firms produce low-ash varieties of activated carbon by removal of various impurities by washing with water or acids such as hydrochloric or nitric acid. If the activated carbon is to be used for the production of fine chemicals or pharmaceutical preparations, a particularly thorough washing procedure is required, and activated carbons for use as catalysts or catalyst support require similar treatment. Basic constituents and accelerators such as caustic potash may be neutralized by acid or washed out with water. Active carbons with fine pores, made by steam activation at 800 °C, can be further activated by air at 500 – 600 °C in the presence of alkali, giving improved decolorizing ability. However, this two-stage activation process has no known practical importance. The most important result of a postoxidation of activated carbon by nitrous gases, in particular nitrogen dioxide, is the formation of additional surface oxides rather than any further activation. The opposite effect, i.e., the removal of chemically bound oxygen, is possible by treating activated carbon with hydrogen at 200 – 500 °C. Lowering of sulfur content can be achieved by the action of steam and hydrogen. In the literature a method is described of producing activated carbon with a low iron content. This involves converting the iron into volatile compounds by treating the carbon while it is still hot with suitable gases or vapors such as halogens, halogen compounds, or carbon monoxide.

5.3.8. *Impregnation*

For cost-effective removal of certain impurities contained in gases (e.g., hydrogen sulfide, mercury, and ammonia), the adsorption capacity and removal rate must be substantially increased by impregnation of the activated carbon with suitable chemicals. When these chemicals are deposited on the internal surface of the activated carbon, the removal mechanism also changes. The impurities are no longer removed by adsorption but by chemisorption [397].

For the manufacture of impregnated activated carbon, an activated carbon of suitable quality for the particular application is impregnated with solutions of salts or other chemicals which, after drying or other aftertreatment steps, remain on the internal surface of the activated carbon. As well as soaking impregnation, spray impregnation can be used. In that case the activated carbon is sprayed in a rotary kiln or in a fluidized bed under defined conditions. The impregnated wet activated carbon must be dried in, for example, a rotary kiln or fluidized-bed drier. After the drying step, most impregnated activated carbons can be used industrially. In some applications the impregnating agents are present in the form of hydroxides, carbonates, chromates, or nitrates and must be subjected to thermal aftertreatment at higher temperatures (150 – 400 °C) to decompose the anions. Depending on the application, various activated carbons (pellets, granules, powders) are impregnated with suitable organic or inorganic chemicals. Homogeneous distribution of the impregnating agents on the internal surface of an

activated carbon is important. Furthermore, blocking of the micropores and macropores must be avoided so that the impregnating agent remains accessible for the reactants.

5.4. Applications

Since the range of applications for carbonaceous adsorbents in the gas and liquid phases is very broad only a small selection can be dealt with here. The major applications are in water treatment, gas purification, food processing, gold recovery, and solvent recovery (Fig. 46).

Figure 46. Gas- and liquid-phase applications of carbonaceous adsorbents

5.4.1. *Gas-Phase Applications*

The majority of gas- and vapor-phase applications of activated carbon are in process gas purification, air purification, catalysis, flue gas purification, solvent recovery, and automotive emission control, and personal protection (Fig. 47).

Figure 47. Gas-phase applications of carbonaceous adsorbents

5.4.1.1. *Solvent Recovery*

Activated carbon can be used advantageously for the removal of organic vapors from gases, its performance being good even at very low partial pressures. This may be deduced from the linear adsorption isotherm plotted in Figure 48. For example, a pelletized activated carbon is able to take up ca. 18 % of its mass of toluene from a current of air that contains only 0.11 g of toluene per m^3. This represents an enrichment factor of over 400 000 : 1. This ability to concentrate a substance is particularly useful for producing extremely pure gases, as well as for protecting the environment [366], [398-402].

Figure 48. Linear adsorption isotherm for toluene

When activated carbon is used for the recovery of solvents, which usually occurs at concentrations between 1 and 20 g/m^3, efficiencies of > 90 % are sought. The cost of regeneration, whether by steam, hot gas, or electrical heating, is usually small in comparison to the value of the recovered solvent. The charge of activated carbon retains its effectiveness for a long time if the regeneration is carried out at a sufficiently high temperature. However, fine material which is formed by attrition and thermal or chemical stress must be removed and replaced from time to time. A survey of some areas of application of solvent recovery is given in Table 17.

Table 17. Solvent recovery

Industry	Typical solvents
Plastic film and foil	ether, acetone, methyl ethyl ketone, alcohols, methylene chloride, tetrahydrofuran, cyclohexanone
Printing	toluene, petroleum spirit, trichloroethene, *n*-hexane
Metal degreasing	trichloroethane, trichloroethene, tetrachloroethene
Rubber	petroleum spirit, benzene, toluene
Viscose and rayon	carbon disulfide
Dry cleaning	tetrachloroethene, fluorochloro hydrocarbons
Synthetic leather and fibers	alcohol, acetone, hexane, toluene, esters, dimethylformamide
Adhesives	petroleum spirit, hexane, toluene

In industry, the solvent recovery is carried out in vertical or horizontal adsorbers, and by arranging these in parallel a continuous operation is possible by changing over from one to another (Fig. 49) [373]. The gas flow is usually in an upward direction, whereas the desorption with hot steam is in the opposite direction. In Figure 50 a typical temperature – time graph for a cycle is given. Usually, fixed-bed adsorbers have a bed thickness of 0.8 – 2 m. A more recent development is the use of fluidized-bed reactors with finely granulated activated carbon [402]. Another development is the use of activated carbon fibers. Both methods are, however, rarely used.

Figure 49. Flow sheet of a solvent recovery unit

a_1) Adsorber 1; a_2) Adsorber 2; b) Exhaust air; c) Blast; d) Desorption; e) Condenser; f) Cooler; g) Separator

Figure 50. Temperature diagram for the carbon bed of a solvent recovery unit

a) Upper part; b) Middle; c) Lower part

Practical solvent recovery systems use gas flow rates of 0.2 – 0.5 m/s. Lower flow rates would lead to better utilization of the adsorption capacity of the carbon, but there is a danger that the heat of adsorption is not carried away, and therefore overheating and even ignition of the carbon charge can occur. Typical operating data for solvent recovery plants and design ranges are given in the following:

Air velocity	0.2 – 0.4 m/s
Air temperature	20 – 40 °C
Bed height	0.8 – 1.5 m
Steam velocity	0.1 – 0.2 m/s
Time cycle per adsorber	
Adsorption	2 – 6 h
Drying (hot air)	0.2 – 0.5 h
Cooling (cold air)	0.2 – 0.5 h
Solvent concentration	1 – 10 g/cm^3
Solvent adsorbed per cycle	10 – 25 wt %
Steam/solvent ratio	(2 – 5):1
Energy	50 – 600 kWh/t solvent
Cooling water	30 – 100 m^3/t solvent
Activated carbon	0.5 – 1 kg/t solvent

Recovery units have at least two, but more usually three or four adsorbers which pass successively through the stages of the operation cycle. While adsorption takes place in one or more of them, desorption, drying, and cooling are carried out in the others.

5.4.1.2. *Process-Gas and Air Purification*

Many *gas purification* processes use activated carbon, e.g., for production of pure gases in the chemical industry, in protection against poison gas, in air conditioning, for removal of oil from compressed air, and in purification of waste air. Small traces of unwanted gases or vapors are adsorbed onto activated carbon which is often improved by being specially impregnated, in which case regeneration with recovery of the extracted materials is impossible. Activated carbon is also used to remove resin-forming and other hydrocarbons from gases before passing them over sensitive molecular sieves or catalysts [366], [373], [396-401].

Small amounts of hydrogen sulfide can be converted to elemental sulfur in the presence of oxygen by means of activated carbon which has been impregnated with potassium iodide [401]. This reaction is used in the viscose industry for purification of waste air. In this case, it is combined with carbon disulfide recovery and is known as the Sulfosorbon process [401], [403]. The Sulfren process uses sulfur dioxide as an oxidizing agent.

Sulfur compounds such as carbon disulfide, carbonyl sulfide, and organic thiols are removed from moist gases containing excess oxygen at high temperature on alkaline carbon. This is the Desorex process. The adsorbate is hydrolyzed and oxidized to sulfate, which can be washed out.

In *air-conditioning* installations, activated carbon is used for the purification of air drawn in from outside, e.g., in airports, near chemical plants, or for environmentally controlled rooms of hospitals or museums. By the use of activated carbon, the amount of necessary cold outside air can be reduced. Because of the large quantities of air to be handled for such large spaces, a small resistance to flow is required, and therefore, thin layers of carbon are used. Often exchangeable cartridge filters are used, and complete filter elements made of specially shaped activated carbon bodies are available. Composite materials have been produced, in which powdered activated carbon is bonded onto polyurethane foam or some other suitable carrier. For the removal of some substances, impregnated activated carbons like those in industrial respirators are used.

In *nuclear power installations*, activated carbon impregnated with iodine compounds is used to remove radioactive iodine compounds from the air exhausted to the atmosphere. This takes place by isotope exchange. In some countries impregnation with the base tetraethylenediamine (TEDA) is used for the same purpose; in this case the iodine compounds are removed by salt formation. Activated carbon is also used in off-gas delay beds. Deep beds of activated carbon with very fine pores adsorb radioactive gases such as krypton and xenon long enough for the isotopes to decay to safe levels of radioactivity, after which they can be released into the atmosphere.

Since World War I, activated carbon filters have been used by the armed forces for *respirators*, and this use has since been extended to protection against hazardous gases in industry. For both applications, virtually complete removal of impurities is necessary, and therefore, only fine-grained activated carbon can be used so as to make a filter as compact as possible. Table 18 shows how the service time depends on the grain size. For respirators, impregnation of activated carbon with chromium and copper salts is a well-proven technology; due to the toxicity of chromium compounds the latest impregnations are based on copper and molybdenum salts. These substances have a strong oxidizing action and high reactivity toward chlorine, hydrogen cyanide, and their derivatives. Other substances used for impregnation are caustic potash (acidic gases), zinc salts (ammonia and hydrogen sulfide), and iodine compounds (mercury vapor).

Table 18. Effect of grain size on the service time of a respirator fitted with an activated carbon filter (test gas: chloropicrin in moist air)

Diameter of carbon granules	mm	0.8	1.2	1.6	2.5	4.0
Service time	min	75	60	35	18	5

Activated carbon and impregnated activated carbon is also used for many odor emission control applications: wood chip drying (pinene, terpene), plastic processing (styrene, benzene, etc.), home application (kitchen hood, refrigerator). Apart from physisorption, chemisorption on impregnated activated carbon (Section Impregnated Activated Carbon) can be applied, especially for H_2S and mercaptan removal.

In cigarette filters and in attachments for tobacco pipes, activated carbon is used to reduce the nicotine and tar content of the smoke.

5.4.1.3. *Gas Separation*

In 1960 the first pressure-swing adsorption (PSA) plants for gas drying, gas purification and gas separation were built. All PSA processes have in common that adsorption is operated at a higher and desorption at a lower total pressure. In the majority of processes the adsorption pressure is markedly higher than atmospheric pressure. For desorption the pressure is either reduced to atmospheric pressure or vacuum is applied to lower the pressure below atmospheric pressure. In some processes, desorption is boosted by a flushing cycle. The pressure-swing adsorption cycle comprises the following steps:

- Adsorption at higher pressure
- Desorption by pressure reduction
- Flushing with product gas
- Pressure build-up with raw gas or product gas to adsorption pressure

Intervals between these individual steps are quite short (30 s to a few minutes) and depend on the separation process and plant design.

Several types of product gases can be obtained during the absorption or desorption step, see Table 19 [396], [405].

Table 19. Selected application fileds for pressure-swing processes for gas separation

Separation problem	Adsorbent **	Production phase *
Gas drying	Al_2O_3, SiO_2, ZMS	A
Hydrogen from coke-oven or reformer gas	CMS, ZMS, Al_2O_3	A
Helium from diving gases	CMS, ZMS, Al_2O_3	A
Nitrogen from air	CMS	A
	ZMS	D
Oxygen from air	CMS	D
	ZMS	A

Methane from biogas	CMS	A
Carbon dioxide from exhaust gas	CMS, ZMS	D

*A = adsorption phase, D = desorption phase.
**Al_2O_3 = aluminium oxide; CMS = carbon molecular sieves; SiO_2 = silica; ZMS = zeolitic molecular sieves.

For gas separation, carbon molecular sieves or activated carbons with extremely fine pores and molecular sieve properties are used. From a mixture of hydrogen, carbon monoxide, and methane, it is possible to produce highly pure hydrogen by adsorption of CO and CH_4 under pressure (1.5 – 4.0 MPa). If pure hydrogen is then passed through in the opposite direction at lower pressure (0.2 – 0.5 MPa), the adsorbed substances are again desorbed. Since the holding time of an adsorber which operates in this PSA mode is in the range of 30 s to a few minutes, a large number of adsorbers (8 – 16) are used in rotation, so that pressure changes can be minimized between the adsorbers and compression energy can be saved. The method can be used to separate oxygen and nitrogen, as well as for production of synthetic natural gas from biogas (biologically produced methane).

5.4.1.4. *Gasoline Vapor Adsorption*

Gasoline vapors evaporate during manufacture, distribution, refueling, and running of cars and enter the environment. Vapor recovery units are installed at tank farms and distribution terminals of refineries. These waste air streams, saturated with organic vapors, are often cleaned by combined processes [406]:

- Absorption and pressure-swing adsorption
- Membrane permeation and pressure-swing adsorption
- Condensation and adsorption

To avoid pollution of the environment by gasoline vapor from motor vehicles, installation of an activated carbon filter in the ventilation port of the gasoline tank is required in the United States, the EU, and Japan. When a car is left standing in the hot sun, for example, the gasoline that evaporates from the tank is adsorbed by the activated carbon and then desorbed again when the vehicle runs and fresh air for the engine is drawn through the carbon cartridge.

5.4.1.5. *Flue Gas Cleaning*

For SO_2 and NO_x removal from flue gases from power plants and waste incineration plants many activated carbon/activated coke processes have been developed. The adsorption capacity of activated carbon and activated coke for sulfur dioxide from flue gas is only a few percent by weight. Therefore, processes are based on the ability of activated coke to oxidize sulfur dioxide in the presence of oxygen, forming sulfuric acid.

$$2\,SO_2 + O_2 + 2\,H_2O \rightarrow 2\,H_2SO_4$$

The spent activated coke can be regenerated thermally at 400 – 500 °C in a desorber; the carbon of the activated carbon skeleton is used as a reactant.

$$2\,H_2SO_4 + C \rightarrow 2\,SO_2 + CO_2 + 2\,H_2O$$

This carbon consumption results in a larger inner surface area and higher catalytic activity, converting the activated coke to activated carbon. The SO_2-rich gas can be processed to elemental sulfur or sulfuric acid.

The catalytic properties of activated carbon are used for catalytic NO reduction by addition of gaseous ammonia.

$$4\,NO + 4\,NH_3 + O_2 \rightarrow 4\,N_2 + 6\,H_2O$$

Activated coke processes for simultaneous SO_2 and NO_x removal are the Mitsui Mining Process, the Sumitomo Heavy Process, and the Uhde/Bergbau-Forschung/Mitsui Process [407]. In the Sulfacid process, which is designed for SO_2 removal, regeneration by water extraction continuously yields dilute sulfuric acid [401].

In waste incineration plants, powdered activated carbon is injected into the flue gas stream through an atomizer. The loaded adsorbent is collected in a fabric filter; further pollutant removal takes place in the filter cake deposited on the fabric [408].

5.4.2. ***Liquid-Phase Applications***

Liquid-phase applications are estimated to account for over two-thirds of world activated carbon consumption; both granular and powdered activated carbons are in use [366], [368], [369], [399], [410].

There are many processes available for treatment of liquids and solutions with activated carbon which have found wide industrial application. In the *batch contact unit operation*, powdered activated carbon is added to the liquid being treated, either directly or (more usually) as a previously prepared suspension. The temperature is raised to reduce the viscosity and hence also the diffusion time. Equilibrium is normally reached after 15 – 30 min, after which the mixture is filtered, usually after adding a filtration aid such as diatomite.

In *continuous-layer filtration*, the liquid is pumped through a prepared bed of powdered carbon, which is usually made more permeable by the addition of diatomite. Due to the short contact time, the purification process is usually incomplete, and because of the limited amount of carbon present in the bed, the operating life is short. The method is used for liquids with only low levels of impurities or for purification of working liquids which can be pumped so as to bypass the filter, e.g., in

electroplating, in swimming baths, or in dry cleaning machines.

Percolation through granular carbon is used particularly in the field of water purification and decolorization. This continuous process has the advantage that large charges of carbon can be employed, particularly when several filters are arranged in series. Depending on the concentration and viscosity of the solution, the contact time in the percolation process can range from 10 min to more than 1 h. In some applications catalytic side reactions such as oxidation may occur, or changes of pH can be brought about by the ash content of the carbon.

Activated carbon and activated coke are often used in combination with other filter materials in multilayer filters for wastewater and drinking water treatment [411].

5.4.2.1. *Water Treatment*

Water treatment (35 % of world consumption) can be divided into drinking water, industrial and municipal wastewater, and groundwater.

In *drinking water*, activated carbon is used to remove unpleasant odors and tastes and reduce the concentration of compounds constituting a health hazard (pesticides, chlorinated hydrocarbons, etc.).

Powdered activated carbon is often used to solve temporary pollution problems and is added to the water as a slurry at the same time or just before adding of flocculant. After a suitable contact time, the powdered activated carbon is removed with the flocculant by sedimentation.

When granular activated carbon is used to purify drinking water, after a rapid gravity sand filtration (removal of suspended solids) the percolation process is used almost exclusively, and in addition to the adsorptive purification, the catalytic decomposition of the oxidizing agents chlorine, chlorine dioxide, and ozone plays an important role. The filtration velocities are between 5 and 20 m/h, which for a layer depth of 2 – 4 m corresponds to a contact time of 6 – 48 min. The backwashing velocities are 40 – 50 m/h. After a service life of 6 – 24 months, the spent carbon is reactivated in a on-site reactivation plant or in the supplier's reactivation plant.

Figure 51 compares the different treatment steps of drinking water with powdered (PAC) and granular activated carbon (GAC).

Figure 51. Drinking-water treatment with powdered and granular activated carbon

The complex composition of *industrial wastewaters* and dumpsite leachates mostly requires a combination of various purification methods to obtain the required purity economically. A combination of activated carbon and biological purification is suitable in many cases. Powdered activated carbon (PAC) is added to aerobic or anaerobic biological treatment plants to adsorb toxic contaminants and stabilize the biological activity. There is then no impairment of the biological activity, and the impurity-loaded carbon is removed along with the microorganisms and usually incinerated. PAC is also used independently in treatment plants [412]. Granular activated carbon filter beds are often used as a tertiary treatment after conventional secondary biological treatment. Industrial wastewaters may exhibit several times higher concentrations of organic substances than drinking water. Even though these differences in concentration are accommodated in plant design (contact time 0.5 – 4 h, filtration velocities of 2 – 6 m/h), the adsorption lifetime of the activated carbon filters is reduced from several months to few days. Accordingly, cost-effective use of activated carbon adsorbers only became possible with the development of processes for activated carbon regeneration in the 1980s. *Dump-site leachates* are often purified by biological treatment followed by a filtration or membrane permeation process and an activated carbon step. The main purpose of adsorption on activated carbon is removal of organic halogen compounds.

5.4.2.2. *Micellaneous Liquid-Phase Applications*

Both powdered and granular activated carbon made from a variety of raw materials are used in *food and beverage processing*. Wood-based chemically activated carbons are preferable for the removal of large color bodies and other high molecular mass impurities. Peat- and coal-based steam-activated carbons are used for decolorization and removal of unpleasant tastes, odors, and other low and medium molecular mass impurities. Microporous coconut-shell activated carbons are less efficient in decolorization. Powdered grades are used in batch processes which already require a filtration stage and where the dosage needs to be varied according to different process conditions. The powdered activated carbon is mixed with the liquid to be purified. When the impurities have been adsorbed, the carbon is removed from the solution by filtration or sedimentation, and is then discharged. Granular activated carbons are used where high volumes of liquids of a consistent quality or grade are continuously processed in large quantities. Fixed-bed and moving bed adsorbers are used, and the spent activated carbon can be reactivated on site or by the carbon supplier.

Some products which are purified with activated carbon follow:

Alcoholic beverages	Beer

	Wine
	Vodka
	White rum
	Whisky
Soft drinks	Dechlorination and removal of taste and organic matter from water
	Decolorisation of sugar and fruit juices
Sugar and sweeteners	Cane sugar
	Beet sugar
	Polysaccharides
	Glucose, lactose, maltose, fructose corn syrups
	Xylitol
	Aspartame
Decaffeinated coffee	Caffeine removal by recirculating CO_2 or hot water and adsorption on activated carbon
Edible oils	Coconut oil
	Palm oil
	Fish oil
	Soybean oil
	Olive oil
Flavorings	Yeast extract
	Monosodium glutamate
	Hydrolysed vegetable
	Proteins
Chemicals and pharmaceutical products	Paraffins
	Waxes
	Phosphoric acid
	Sodium hydroxide
	Citric acid
	Gelatin
	Pectin
	Quinine
	Insulin
	Antibiotics
	Sulfonamides

Activated carbon processes have been developed *gold recovery* from low-grade ores. In the carbon-in-pulp process (CIP) a suspension of the ore is treated with cyanide to produce gold cyanide, which is then adsorbed onto granular activated carbon (⟶ Gold, Gold Alloys, and Gold Compounds – Recovery of Gold with Carbon . By using multistage countercurrent adsorption, the gold cyanide complex is concentrated on the activated carbon. The carbon is then separated by mechanical sieving and subjected to a elution process under slight pressure. Gold is recovered from the activated carbon by elution followed by electrowinning. After thermal reactivation the carbon can be re-used in the process. Activated coconut carbon or extruded granular carbon, with high attrition and abrasion resistance, are used.

One of the oldest uses is in *medicine* for the adsorption of harmful bacteria and their metabolic products in the gastrointestinal tract. For blood dialysis treatment in cases of kidney and liver diseases or poisoning, granular activated carbon with a semipermeable coating is used.

5.4.3. *Impregnated Activated Carbon*

Impregnated activated carbon is predominantly used in the following applications:

- Gas purification
- Civil and military gas protection
- Catalysis

For these applications the manufacturers offer various qualities of impregnated activated carbon. Table 20 lists frequently used impregnated activated carbons. A given impregnating agent is frequently used for various purification tasks [397].

Table 20. Commercial grades of impregnated activated carbon [397]

Impregnation

Chemicals	Quantity, wt %	Activated carbon*	Examples for applications
Sulfuric acid	2 – 25	F 1 – 4 mm Ø	ammonia, amine, mercury
Phosphoric acid	10 – 30	F 1 – 4 mm Ø	ammonia, amine
Potassium carbonate	10 – 20	F 1 – 4 mm Ø	acid gases (HCl, HF, SO_2, H_2S, NO_2), carbon disulfide
Iron oxide	10	F 1 – 4 mm Ø	H_2S, thiols, COS
Potassium iodide	1 – 5	F 1 – 4 mm Ø	H_2S, PH_3, Hg, AsH_3, radioactive gases/radioactive methyl iodide
Triethylenediamine	2 – 5	F 1 – 2 mm Ø	radioactive gases/radioactive methyl iodide
		G 6 – 16 mesh	
Sulfur	10 – 20	F 1 – 4 mm Ø, G	mercury
Potassium permanganate	5	F 3 + 4 mm Ø	H_2S from oxygen-lacking gases
Manganese IV oxide		G 6 – 16 mesh	aldehyde
Silver	0.1 – 3	F 3 + 4 mm Ø	F: phosphine, arsine
	0.05 – 0.4	G 8 – 30 mesh	G: domestic drinking water filters (oligodynamic effect)
Zinc oxide	10	F 1 – 4 mm Ø	hydrogen cyanide
Chromium – copper – silver molybdenum salts	10 – 20	F 0.8 – 3 mm Ø	civil and military gas protection
		G 12 – 30 mesh	phosgene, chlorine, arsine
		G 6 – 16 mesh	chloropicrin, sarin, and other nerve gases
Mercury (II) chloride	10 – 15	F 3 + 4 mm Ø	vinyl chloride synthesis, vinyl fluoride synthesis
Zinc acetate	15 – 25	f 3 + 4 mm Ø	vinyl acetate synthesis
Noble metals	0.5 – 1.0	F, G, P	organic synthesis, hydrogenation
(palladium, platinum)	0.5	G 2 – 5 mm	purification of terephthalic acid

*F = pelletized activated carbon, G = granulated activated carbon, P = powdered activated carbon, Ø = pellet diameter.

Potassium iodide promotes the action of activated carbon as an oxidation catalyst and thus allows catalytic oxidation of hydrogen sulfide to sulfur or of phosphine to phosphoric acid. The same impregnation technique is used to extract radioactive methyl iodide and other gaseous compounds arising in nuclear installations. Hydrogen sulfide and formaldehyde can be oxidized to nonhazardous substances with the aid of activated carbon impregnated with manganese dioxide; at high temperatures the formaldehyde is oxidized not just to formic acid, but directly through to carbon dioxide. Impregnation with iron salts and conversion to iron(III) oxide enables the removal of divalent sulfur compounds from gas mixtures low in oxygen. About 1.5 times the stoichiometric amount of oxygen is required to oxidize these compounds [401]. Activated carbon treated with elemental sulfur is used to eliminate mercury vapor from natural gas, hydrogen, and other gases [409]. Silver-impregnated activated carbon is used for purification of drinking water due to its oligodynamic effect.

5.4.4. *Catalysts and Catalyst Supports*

In addition to its adsorption properties, activated carbon has catalytic properties which allow commercial use as catalyst and catalyst support. The catalytic action of activated carbon is due to the crystalline structure of the skeleton, which consists of a mixture of amorphous and graphitic carbon. On the rims of the layers, there are many unsaturated edges and ridges which act as lattice vacancies. On the internal activated carbon surface, there are surface oxides, which have been identified as carbonyl groups, lactone groups, phenolic hydroxyl groups, and carboxyl groups [370], [375]. These surface oxides can participate in redox reactions, and they are a reason for the effectiveness of activated carbon catalysts in oxidation reactions. The type and quantity of surface oxides play a part in such oxidation reactions as the conversion of sulfur dioxide to sulfur trioxide or when activated carbon is incorporated into dry cells in conjunction with manganese dioxide for the depolarization process. Activated carbon serves as a catalyst in the synthesis of phosgene from carbon monoxide and chlorine and in the synthesis of sulfuryl chloride from sulfur dioxide and chlorine. The catalytic activity of the carbon is associated with the π electrons in a similar manner as graphite crystals catalyze the trimerization of cyanogen chloride to cyanuric chloride. In each case, weakening of the double bonds in the reactants occurs. In addition, the industrial process in which hydrogen chloride is removed from chloroethane in the presence of activated carbon presumably has a similar mechanism.

By incorporation of heteroatoms the surface of activated carbon can be modified to achieve very high activity for redox reactions such as the decomposition of chloramines and the oxidation of H_2S or SO_2. When these catalytic/adsorptive carbons are used for removal of sulfur compounds, the end product is sulfuric acid, which can be washed out with water.

Some types of activated carbon are used as catalyst support for industrial syntheses of vinyl acetate and vinyl chloride. Activated carbon is particularly suitable as catalyst support because, in contrast to oxidic catalyst supports, it has no Lewis acidity and therefore does not lead to unwanted polymerization of the vinyl monomers. Vinyl acetate is produced by vinylation of acetic acid with acetylene in a heterogeneous catalytic gas-phase reaction in presence of a zinc acetate/activated carbon catalyst at 160 – 240 °C. Vinyl chloride can be produced by direct catalytic addition of hydrogen chloride to ethyne at 120 – 150 °C in the presence of an activated carbon impregnated with about 10 % of mercury(II) chloride is used as catalyst.

Catalysts for various purposes are obtained by depositing noble metals on activated carbon. A well-known example is palladium-coated activated carbon powder [7440-05-3], a typical hydrogenation catalyst for use in suspension.

In the Merox process for oxidation of mercaptans in mineral oil, activated carbons impregnated with cobalt phthalocyanine [3317-67-7] are used.

5.5. Regeneration and Reactivation

The use of activated carbon for gas and water cleaning in industries and environmental protection is particularly economical if suitable processes for the regeneration of spent activated carbon are available. Generally for the regeneration of the spent carbon pressure swing, thermal desorption, extraction, or thermal reactivation processes are used (Table 21) [366-369], [410].

Table 21. Regeneration of spent activated carbon

Process	Basic concept	Main applications
Pressure-swing adsorption	adsorption at higher pressure, desorption at low pressure	hydrogen purification, air separation (oxygen/nitrogen), methane enrichment from biogas, gasoline vapor recovery
Thermal desorption	steam desorption at 100 – 150 °C, inert gas desorption at 150 – 250 °C	solvent recovery, (toluene, alcohols, hydrocarbons, etc.)
Extraction	elution of organics by solvents or alkali	phenols by alkaline extraction, sulfur extraction with CS_2
Thermal reactivation	selective gasification of carbonized residues and carbon deposits by steam at 800 – 900°C	spent activated carbon from water treatment and other applications

If the adsorbate is bound reversibly onto the surface of the adsorbent the activation energy E_{des} is required for desorption only. For low values of E_{des} (10 – 30 kJ/mol), as in gas separation processes, desorption can be achieved by lowering the pressure in a PSA process.

For adsorptive removal and recovery of solvent, a higher energy of desorption (30 – 60 kJ/mol) is needed for desorption. Usually, superheated steam or hot inert gas is passed through the carbon bed, and this also removes the desorbed substances from the intergranular spaces.

Apart from thermal desorption, extraction with solvents can be used to remove adsorbed substances from used carbons. For example, the elemental sulfur produced in the Sulfosorbon process can be extracted by carbon disulfide. In the literature solvents such as dimethylformamide, acids, and alkali solutions are described [366], [367].

The success of activated carbon in drinking-water and wastewater treatment has been due to the development of regenerable activated carbon types and the development of effective processes for the regeneration of the spent carbon. Spent activated carbon used in water treatment usually contains many different kinds of organic substances. A complete thermal desorption of all adsorbed substances is not possible. The decomposition temperatures of high molecular mass compounds are below the desorption temperature. Thus a residual load consisting of pyrolysis products and carbon deposits remains on the internal surface of the activated carbon. These spent activated carbons are thermally regenerated at 800 – 850 °C in a process that is similar to the production of activated carbon and hence more properly called reactivation. Independent of the reactor type used, the spent activated carbon passes through four main steps during the temperature rise to 850 °C:

≤ 100 °C	water removal
100 – 350 °C	desorption of low-boiling organic compounds
350 – 800 °C	thermal cracking of high molecular mass compounds
800 – 850 °C	gasification of the pyrolysis product and carbon deposits by H_2O and CO_2

Investigations have shown that carbonaceous deposits formed by thermal desorption treatment of the residual load show a higher reactivity due to their disturbed structure than the carbon surface of the activated carbon. Under such conditions, the loaded activated carbon can be selectively treated with the water gas shift reaction at ca. 800 °C, which restores the original surface structure and adsorption performance of the activated carbon. Drying, desorption, thermal cracking, and gasification can be performed in a single industrial reactor. All types of furnaces used for activation of activated carbon can be used for

reactivation. Fluidized-bed reactors, rotary kilns, and multiple-hearth reactors are widely used.

Some methods for regenerating powdered carbons have been proposed in the past, but these have not yet attained widespread practical application. To date, powdered activated carbon has only been reactivated in a few cases.

5.6. Economic Aspects

World consumption of activated carbon was estimated at 450 000 t in 1998, and capacity utilization of the activation plants at 70 – 80 %. Percentage consumption (1998) by region was estimated as United States 37 %, Europe 32 %, Japan 18 %, rest of the world 13 %. World demand was forecast to rise by 2 – 3 % per annum. Areas of potential growth are flue gas purification in Europe and Japan, water treatment in the United States, Europe, and Japan, and automotive emission control.

The regeneration of spent granular activated carbon (Europe: 50 000 – 60 000 t/a) is a growing market in all areas, but increased regeneration will lead in a fall in the rate of growth in demand for virgin material.

Worldwide there are more than 100 activated carbon producers, but the ten largest producers account for about 70 % of world capacity. About 45 % of production is powdered activated carbon and about 55 % is granular and extruded activated carbon (pellets). The largest producers, divided by country, are given in the following:

America	
USA	Anticarb
	Barnebey and Sutcliffe Corp.
	Calgon Carbon Corp.
	Norit America Inc.
	Westvaco Corp.

6. Carbon Black

Manfred Voll and Peter Kleinschmit

Carbon black [1333-86-4] and soot are formed either by pyrolysis or by partial combustion of vapors containing carbon. Soot as an unwanted byproduct of combustion (e.g., in chimneys or diesel engines) is a poorly defined material. Besides carbon black particles, it often contains significant amounts of ash and large amounts of polycyclic aromatic hydrocarbons (PAH) [413]. Residual hydrocarbons, which can be determined by extraction with solvents (e.g., toluene), can account for 30 wt %.

On the other hand, the term “carbon black” is used for a group of well-defined, industrially manufactured products, which are produced under carefully controlled conditions. The physical and chemical properties of each grade of carbon black are kept within narrow specifications. Carbon black is one form of highly dispersed elemental carbon with extremely small particles. Depending on the production process and the raw materials, carbon black also contains chemically bound hydrogen, oxygen, nitrogen, and sulfur.

Due to its excellent pigmentation properties, especially its light stability and universal insolubility, carbon black has been used as a black pigment since early times. It was produced for this purpose by burning oils, fats, or resinous materials. The flame was either quenched on a cool surface (impingement black) or cooled in special chimneys (lamp black), where the carbon black was deposited.

Both processes are still used for the production of carbon black. The channel black process, a process for making impingement blacks, has been used in the United States since the end of the 19th century. This process, which has now been abandoned because of economic and environmental considerations, used natural gas as raw material. A similar process for the production of impingement blacks, the “Degussa gas black process,” is still used today.

The increasing demand for carbon black led to new production processes. The most important process today is the furnace black process. It was developed in the United States in the 1930s and substantially improved after World War II. It is a continuous process, which allows the production of a variety of carbon black grades under carefully controlled conditions. Nearly all rubber grades and a significant part of pigment-grade carbon blacks are now manufactured by the furnace black process. Nevertheless, other processes, such as gas black, lamp black, thermal black, and acetylene black processes, are still used for the production of specialties.

While carbon black was exclusively used as a pigment until the beginning of this century, its use as an active filler in rubber was the starting point for a new rapidly expanding application. In the production of automobile tires, it was found that treads filled with carbon black had a markedly higher abrasion resistance than those filled with zinc oxide. This discovery, together with increasing use of motor vehicles, was the basis for the present importance of carbon black as a filler in rubber.

Today at least 35 different grades of carbon black are used as fillers in rubber, and about 80 are used in pigments or special applications. The total world production in 1994 was 6×10^6 t, of which ca. 90 % was used in the rubber industry.

6.1. Physical Properties

Morphology. Electron micrographs show that the primary particles of carbon black are almost spherical. In general, a larger number of such primary particles builds aggregates in the form of chains or clusters. In practice, the degree of aggregation is called the “structure” of carbon black. These aggregates tend to agglomerate.

The mean primary particle diameter, the width of the particle size distribution, and the degree of aggregation can be varied within relatively wide ranges (Figs. 52-54) by varying the production process and several process parameters.

Figure 52. Carbon blacks of different primary particle sizes and specific surface areas

From left to right: lamp black (mean primary particle diameter 95 nm, BET surface area 21 m^2/g), furnace black (27 nm, 90 m^2/g), finely divided gas black (13 nm, 320 m^2/g)

Figure 53. Particle distribution curves for the carbon blacks of Figure 52

Figure 54. Furnace blacks of different aggregation degrees

The diameter of the primary particles ranges from 5 to 500 nm. Diffraction patterns produced by the so-called phase-contrast method in high-resolution electron microscopy show that the spherical primary particles are not amorphous (Fig. 55). They consist of relatively disordered nuclei surrounded by concentrically deposited carbon layers [414]. The degree of order increases from the center to the periphery of each particle, a phenomenon important to the understanding of the chemical reactivity of carbon black.

Figure 55. Phase-contrast electron micrograph of a carbon black aggregate

The carbon atoms within each layer are arranged in almost the same manner as in graphite. The layers are almost parallel to each other; however, the relative position of these layers is random, so that there is no order as in the *c* direction of graphite (“turbostratic structure”) [415]. X-ray diffraction permits the determination of “crystalline” regions within the carbon black primary particle. These regions are parts of more extended layers, not isolated crystallites. X-ray diffraction reflexes are observed wherever parts of at least three layers are parallel and equidistant. For most carbon blacks, these “crystalline” regions are 1.5 – 2.0 nm in length and 1.2 – 1.5 nm in height, corresponding to 4 – 5 carbon layers [416]. The fraction of “crystalline” or well-ordered carbon in carbon blacks varies according to oxidation kinetic studies between 60 and 90 %.

The morphology of carbon black primary particles indicates that during formation of carbon black, the first nuclei of pyrolyzed hydrocarbons condensate from the gas phase. Thereafter, further carbon layers or their precursors are adsorbed onto the surface of the growing particle. Due to this adsorption, the new layers are always orientated parallel to the existing surface. In the case of high-structure carbon blacks, several particles are joined by collision while they grow. Aggregates are formed by further carbon deposits on these initially loose agglomerates. Polyacetylene seems to play a role in the formation of precursors when aliphatic hydrocarbons are used as starting materials. With aromatic raw materials, however, it is more likely that aromatic degradation products are the intermediates.

The carbon layers of carbon black rearrange to a graphitic order, beginning at the particle surface at temperatures above 1200 °C. At 3000 °C, graphite crystallites are formed and the carbon black particles assume polyhedral shape.

Specific Surface Area. The specific surface area of industrial carbon blacks varies widely. While coarse thermal blacks have specific surface areas as small as 8 m^2/g, the finest pigment grades can have specific surface areas as large as 1000 m^2/g. The specific surface areas of carbon blacks used as reinforcing fillers in tire treads lie between 80 and 150 m^2/g. In general, carbon blacks with specific surface areas > 150 m^2/g are porous with pore diameters of less than 1.0 nm. The area within the pores of high-surface-area carbon blacks can exceed the outer (geometrical) surface area of the particles.

Adsorption Properties. Due to their large specific surface areas, carbon blacks have a remarkable adsorption capacity for water, solvents, binders, and polymers, depending on their surface chemistry. Adsorption capacity increases with increasing specific surface area and porosity. Chemical and physical adsorption not only determine wettability and dispersibility to a great extent, but are also most important factors in the use of carbon blacks as fillers in rubber as well as in their use as pigments. Carbon blacks with high specific surface areas can adsorb up to 20 wt % of water when exposed to humid air. In some cases, the adsorption of stabilizers or accelerators can pose a problem in polymer systems.

Density. Density measurements using the helium displacement method yield values between 1.8 and 2.1 g/cm^3 for different grades of carbon black. A mean density value of 1.86 g/cm^3 is commonly used for the calculation of electron microscopic surface areas. Graphitization raises the density to 2.18 g/cm^3. The lower density with respect to graphite (2.266 g/cm^3) is due to slightly greater layer distances.

Electrical Conductivity. The electrical conductivity of carbon blacks is inferior to that of graphite, and is dependent on the type of production process, as well as on the specific surface area and structure. Since the limiting factor in electrical conductivity is generally the transition resistance between neighboring particles, compression or concentration of pure or dispersed carbon black, respectively, plays an important role. Special grades of carbon black are used to give polymers antistatic or electrically conductive properties. Carbon blacks with high conductivity and high adsorption capacity for electrolyte solutions are used in dry-cell batteries.

Light Absorption. The wide use of carbon blacks as black pigments is due to their absorption of visible light. The absorption rate can reach 99.8 %. The black color can take on a bluish or brownish tone, depending on light scattering, wavelength, the type of carbon black, and the system into which the carbon black is incorporated. Infrared and ultraviolet light is also absorbed. Therefore, some carbon blacks are used as UV stabilizers in plastics.

6.2. Chemical Properties

Chemical Composition and Surface Chemistry. The global chemical composition according to elemental analysis is within the following limits:

carbon. 80.0 – 99.5 wt %
hydrogen. 0.3 – 1.3 wt %
oxygen. 0.5 – 15.0 wt %
nitrogen. 0.1 – 0.7 wt %
sulfur. 0.1 – 0.7 wt %

depending on the manufacturing process, raw material, and possible chemical aftertreatment. The ash content of most furnace blacks is < 1 wt %. The ash components can result from the raw material, the salts which are injected to control the structure, and salts in the process water. The ash content of gas blacks is less than 0.02 %.

The surface of carbon blacks contains certain amounts of polynuclear aromatic substances. These are strongly adsorbed and can only be isolated by continuous extraction with solvents, e.g., boiling toluene. For most industrial pigment-grade carbon blacks, the amount of extractable material is below the limit defined by the food laws.

The hydrogen in carbon black is bound as CH groups at the edge of the carbon layers. Nitrogen seems to be primarily integrated into the aromatic layer system as heteroatoms.

The oxygen content of carbon blacks is of great importance for their application. Oxygen is bound to the surface in the form of acidic or basic functional groups. The amount of surface oxides and their composition depend on the production process and an eventual aftertreatment. Furnace blacks and thermal blacks, which have been produced in a reducing atmosphere, contain about 0.2 – 2.0 wt % oxygen in the form of almost pure, basic surface oxides. Gas and channel blacks, which are manufactured in the presence of air, contain up to 8 wt % oxygen. In this case, the greater part of the oxygen is contained in acidic surface oxides and only a small portion in basic oxides. The amount of acidic surface oxides can be increased by oxidative aftertreatment, in which oxygen contents of up to 15 wt % can be obtained.

The surface oxides are destroyed at high temperatures. Due to this fact the weight loss at 950 °C (“volatiles”) is a rough indication of the oxygen content of a carbon black.

The pH measured in an aqueous slurry is another indication of the degree of oxidation. In general, the pH is > 7 for furnace blacks (low oxygen content, basic surface oxides), 4 – 6 for gas blacks, and 2 – 4 for oxidized carbon blacks (high oxygen content, acidic surface oxides with a high amount of polar functional groups). Further organic reactions, e.g., alkylation, halogenation, esterification, can be carried out with the surface oxides to modify the surface properties.

Oxidation Behavior. Industrial carbon blacks do not spontaneously ignite when stored in air at 140 °C according to IMCO Code [417]. When ignited in air, carbon black glows slowly. In contrast to coal, dust explosions are not observed under normal test conditions [418]. However, ignition sources of extremely high energy, e.g., a gas explosion, may induce a secondary dust explosion in air.

For modification of the application properties with regard to surface oxidation, see Section Oxidative Aftertreatment of Carbon Black .

6.3. Raw Materials

Mixtures of gaseous or liquid hydrocarbons which can be vaporized represent the raw materials preferable for the industrial production of carbon black. Since aliphatic hydrocarbons give lower yields than aromatic hydrocarbons, the latter are primarily used. The best yields are given by unsubstituted polynuclear compounds with 3 – 4 rings. Certain fractions of coal tar oils and petrochemical oils from petroleum refinement or the production of ethylene from naphtha (aromatic concentrates and pyrolysis oils) are materials rich in these compounds. These aromatic oils, which are mixtures of a variety of substances, are the most important feedstocks today. Oil on a petrochemical basis is predominant. A typical petrochemical oil consists of 10 – 15 % monocyclic, 50 – 60 % bicyclic, 25 – 35 % tricyclic, and 5 – 10 % tetracyclic aromates.

Important characteristics determining the quality of a feedstock are the C/H ratio as determined by elemental analysis and the BMCI [419] (Bureau of Mines Correlation Index), which is calculated from the density and the mid-boiling point or from the

density and the viscosity. Both C/H ratio and BMCI values give some information on the aromaticity and therefore the expected yield. Further characteristics are viscosity, pour point, temperature of solidification, alkaline content (due to its influence on the carbon black structure), and sulfur content, which should be low because of environmental and corrosion considerations.

Natural gas, which was previously the predominant feedstock for the production of channel blacks and furnace blacks in the United States, has lost its importance for economic reasons. Only thermal blacks are produced with natural gas. However, natural gas is still the most important fuel in the furnace black process, although other gases and oils are used in some cases. In several patents, recycled tail gas, in combination with oxygen or oxygen-enriched air, has also been proposed as a fuel, but has not gained any commercial importance.

Acetylene, due to its high price, is used only for the production of highly specialized conductivity blacks and battery blacks.

6.4. Production Processes

A summary of the most important production processes is given in Table 22. In general, the processes are divided into two groups: those employing partial combustion and those based on pure pyrolysis. This nomenclature is somewhat misleading insofar as the carbon black resulting from the partial combustion process is also formed by pyrolysis. The two types of processes differ in that air is used in the one to burn part of the feedstock, thus producing the energy required to carry out the pyrolysis, whereas in the other heat is generated externally and introduced into the process.

Table 22. Summary of the manufacturing processes and feedstocks for the production of carbon black

Chemical process	Manufacturing process	Feedstock
Incomplete combustion	furnace black process	petrochemical oils and coal tar oils
	Degussa gas black process	coal tar oils
	channel black process	natural gas
	lamp black process	petrochemical and coal tar oils
Thermal cracking	thermal black process	natural gas, oil
	acetylene black process	acetylene

The furnace black process is currently the most important production process. It accounts for more than 95 % of the total worldwide production. The advantages of the furnace black process are its great flexibility, which allows the manufacture of various grades of carbon black, and its better economy compared to other processes. The following comparison makes this apparent: for similar grades of carbon black, the production rate of one flame is ca. 0.002 kg/h for channel black, ca. 0.2 kg/h for gas black, and ca. 2000 kg/h for a modern furnace black reactor. However, in spite of the more advantageous furnace black process, the production processes listed in Table 22 (except for the channel black process) are still in use for the production of special carbon blacks which cannot be obtained via the furnace black process.

6.4.1. *Furnace Black Process*

In the past decades, the rapidly expanding automobile industry required increasing numbers of tires with various characteristics. This led not only to the development of new rubber grades, but also to the development of new carbon blacks required by the increasingly refined application processes and to the development of a new and better manufacturing process, the furnace black process. Unlike the old channel black process, this process allows the production of virtually all grades of carbon black required by the rubber industry. It also meets the high economic and ecological requirements of our times.

The furnace black process was developed in the United States in the 1920s, and since then, it has been greatly refined. It is a continuous process, carried out in closed reactors, so that all inputs can be carefully controlled [420]. Today most semireinforcing rubber blacks (carcass or soft blacks), with specific surface areas of 20 – 60 m^2/g, and the active reinforcing blacks (tread or hard blacks; see Table 25), with specific surface areas of 65 – 150 m^2/g, are manufactured by this process, as well as an increasing number of pigment-grade carbon blacks with much higher specific surface areas and smaller particle sizes. In addition to the specific surface area, other quality specifications such as structure, as measured by DBP absorption, and application properties such as abrasion resistance, modulus, and tear strength for usage in rubber, or jetness and tinting strength for color blacks, can also be systematically varied in the furnace black process by adjusting the operating parameters. This flexibility is necessary to meet the very narrow specifications required by customers.

The heart of a furnace black production plant is the furnace in which the carbon black is formed. The feedstock is injected, usually as an atomized spray, into a high-temperature zone of high energy density which is achieved by burning a fuel (natural gas or oil) with air. The oxygen, which is in excess with respect to the fuel, is not sufficient for complete combustion of the feedstock, the majority of which is therefore pyrolyzed to form carbon black at 1200 – 1900 °C. The reaction mixture is then quenched with water and further cooled in heat exchangers, and the carbon black is collected from the tail gas by a filter system.

Figure 56 shows a schematic drawing of a furnace black production line. The feedstock, preferably petrochemical or carbochemical heavy aromatic oils, some of which begin to crystallize near ambient temperature, is stored in heated tanks equipped with circulation pumps to maintain a homogeneous mixture. Oil is conducted to the reactor by means of rotary pumps via heated pipes and a heat exchanger, where it is heated to 150 – 250 °C to obtain a viscosity appropriate for atomization. Various types of spraying devices are used to introduce the feedstock into the reaction zone. An axial oil injector with a spraying nozzle which produces a hollow-cone spray pattern, is often used. One- and two-component atomizing nozzles [421] are in use, air and steam being the preferred atomizing agents in the latter case. In other reactors, however, the feedstock is injected as a plurality of coherent or atomized streams into the accelerated combustion gases perpendicular to the direction of stream [422].

As the carbon black structure may be reduced by the presence of alkali metal ions in the reaction zone [423], alkali metal salts, preferably aqueous solutions of potassium hydroxide or potassium chloride, are often added to the make oil in the oil injector. Alternatively, the additives may be sprayed separately into the combustion chamber. In special cases, other additives, e.g., alkaline-earth metal compounds which increase the specific surface area are introduced in a similar manner.

The high temperature necessary for pyrolysis is obtained by burning fuel in excess air in a combustion chamber. Natural gas is still the fuel of choice, but other gases, e.g., coke oven gases or vaporized liquid gas, are occasionally used. Various oils, including the feedstock, are occasionally used as fuel for economic reasons. Depending on the type of fuel, special burners are used to obtain fast and complete combustion.

The air required for combustion is compressed by rotating piston compressors or turbo blowers. The air is preheated in heat exchangers by the hot carbon-black-containing gases leaving the reactor. This saves energy and thus improves the carbon black yield. Preheated air temperatures of 500 – 700 °C are common.

Important progress has been made on the reactor throughput: A production plant with a capacity of 20 000 t/a (2.5 t/h) was originally run with as many as 12 furnaces. In the last decades they have been replaced by a single high-performance reactor for the same capacity. Modern plants are a one-stream configuration with one unit for each process step (reactor, collecting system, pelletizer, dryer). From a technical point of view, even larger units could be built. However, due to the great variety of carbon black grades required, the capacity of one unit is economically limited by the frequency of switching over to other grades and the amount of off-grade carbon black which may be produced during this procedure.

The reactors of modern furnace plants vary considerably in internal geometry, flow characteristics, and the manner in which fuel and feedstock are introduced. Nevertheless, they all have the same basic process steps in common: producing hot combustion gases in a combustion chamber, injecting the feedstock and rapidly mixing it with the combustion gases, vaporizing the oil, pyrolyzing it in the reaction zone, and rapidly cooling the reaction mixture in the quenching zone to temperatures of 500 – 800 °C.

Schematic drawings of some typical modern furnace black reactors are shown in Figure 57. They all have a gas-tight metal jacket. The reaction zone is coated with a ceramic inner liner, generally on an alumina base, which is stable to temperatures of ca. 1800 °C. Several quenching positions allow the effective reaction volume of the reactor to be adjusted. This allows variation of the mean residence time of the carbon black at the high reaction temperature. Typical residence times for reinforcing blacks are 10 – 100 ms.

Figure 57. Furnace black reactors

A) Restrictor ring reactor; B) Venturi reactor [424]; C) Reactor with high-speed combustion chamber [425]a) Feedstock; b) Fuel; c) Combustion air; d) Quench

Most furnace black reactors are arranged horizontally. They can be up to 18 m long with an outer diameter of up to 2 m. Some vertical reactors are used especially for the manufacture of certain semireinforcing blacks [426] (Fig. 58). For further reactors, see [427].

Figure 58. Vertical reactor for manufacturing semireinforcing blacks

a) Fuel inlet; b) Oil injector; c) Air conduit; d) Water spray; e) Outlet to the collecting system

The properties of carbon blacks depend on the ratios of fuel, feedstock, and air, which therefore must be controlled carefully [428]. The particle size of the carbon black generally decreases with increasing amounts of excess air relative to the amount needed for the complete combustion of the fuel. Since the excess air reacts with the feedstock, a greater amount of air leads to higher oil combustion rates, resulting in rising temperatures in the reaction zone. As a consequence, the nucleation velocity and the number of particles formed increase, but the mass of each particle and the total yield decrease. This allows semireinforcing carbon blacks to be manufactured with better yields than active reinforcing carbon blacks.

The yields, which depend on the carbon black type and the type of feedstock, range between 50 and 65 % for semireinforcing blacks and 40 and 60 % for reinforcing blacks. High-surface-area pigment blacks with markedly smaller particle size than rubber blacks give lower yields.

Other parameters influencing carbon black quality are the manner in which the oil is injected, atomized, and mixed with the combustion gases, the type and amount of additives, the preheating temperature of the air, and the quench position. As long as the carbon black is in contact with the surrounding gases at the high reaction temperature, several reactions on the carbon surface occur (e.g., Boudouard reaction, water gas reaction), so that the chemical nature of the carbon black surface is modified with increasing residence time. When quenched to temperatures below 900 °C, these reactions are stopped and a certain state of surface activity is frozen. Carbon black surface properties can also be further modified by varying the pelletizing and drying conditions (see below).

Typical processing data for reactors with a carbon black output of 10 000 t/a (1250 kg/h) of tread black and of 14 000 t/a (1750 kg/h) of carcass black are listed in Table 23. These data show that the total mass put through the reactor amounts to 10 – 16 t/h. Although this is done at high streaming velocities (up to 800 m/s) and high temperatures (up to 1800 °C), modern high-performance reactors can have lifetimes of two years and more.

Table 23. Processing data for high-performance furnace black reactors

		Semireinforcing carbon black	Reinforcing carbon black
Natural gas	m^3/h	300 – 550	280 – 440
Air	m^3/h	7 000 – 10 000	6 000 – 7 500
Oil	kg/h	2 500 – 3 300	2 000 – 3 000
Carbon black	kg/h	1 500 – 2 000	1 000 – 1 500
	t/a	12 000 – 16 000	8 000 – 12 000
Yield	kg/100 kg of oil	50 – 65	40 – 60

The mixture of gas and carbon black leaving the reactor is cooled to 250 – 350 °C in heat exchangers by counterflowing combustion air and then conducted into the collecting system. Formerly, a combination of electroflocculators and cyclones or cyclones and filters were used [420], [429]. Currently, simpler units are preferred. Generally, the collecting system consists of only one high-performance bag filter with several chambers, which are periodically purged by counterflowing filtered gas or by pulse jets. Occasionally, an agglomeration cyclone is installed between the heat exchanger and the filter. Depending on the capacity of the production unit, the filter may contain several hundred bags with a total filter area of several thousand square meters. Usual filter loads are on the order of 0.2 – 0.4 $m^3\ m^{-2}\ min^{-1}$. Since the filtered gas contains 25 – 40 vol % water vapor, most filters operate at temperatures above 200 °C to avoid condensation. The residual carbon black content in the off-gas is less than 10 mg/m^3.

Because of the reducing atmosphere and the high temperatures in the reactor, the tail gas, which consists of 25 – 40 vol% water vapor, 40 – 50 vol % nitrogen, and 3 – 5 vol % carbon dioxide, also contains a certain amount of combustible gases, the amount of which depends on the feedstock and the processing conditions. These gases include 5 – 10 vol% carbon monoxide, 5 – 10 vol % hydrogen, and small amounts of methane and other hydrocarbons. The lower heating value lies between 1700 and 2100 kJ/m^3. The energy remaining in the tail gas can be calculated by using the typical overall energy balance of the furnace black process shown in Figure 59. The gas must be burned for environmental reasons, and its energy is used, e.g., for heating dryer drums or for the production of steam and electricity.

Figure 59. Typical energy balance for the manufacture of a reinforcing black

The fluffy carbon black coming out of the filter is pneumatically conveyed into a first storage tank. Small amounts of solid impurities (“grit,” e.g., iron, rust, or coke particles) are either removed by magnets and classifiers or milled to an appropriate consistency.

Freshly collected carbon black has an extremely low bulk density of 20 – 60 g/L. To facilitate handling and further processing by the customer, it must be compacted. Densification by “outgassing” — a process by which the carbon black is passed over porous, evacuated drums — is the weakest form of compacting and allows the carbon black to retain its powdery state [430]. This form of compacting is used for certain pigment blacks which must retain easy dispersibility.

Other pigment blacks and the rubber blacks are compacted by granulation. Two processes are used: dry and wet pelletization.

Dry pelletizing is a simple and energy-saving method, but it does not work with all types of carbon black. It is mainly used for color blacks. Dry pelletization is carried out in rotating drums, where the powdery carbon black rolls to form small spheres.

The wet pelletization process is used for the majority of rubber blacks. Carbon black, water, and small amounts of additives (e.g. molasses, ligninosulfonates) are mixed in special pelletizers [431]. They usually consist of a horizontal cylinder ca. 3 m long and 0.7 – 1 m in diameter, in the axis of which a pin shaft rotates at 300 – 750 rpm (Fig. 60). The water containing the pelleting agents dissolved in it is injected via spray nozzles. The density of the pelletized material is ca. 10 times that of the original carbon black. DBP absorption is also reduced during this process. The pellet crush strength and some application properties in rubber can be influenced by the type and amount of the pelleting agent. The size of the pellets is ca. 1 – 2 mm.

Figure 60. Pelleting machine

The carbon black leaving the pelleting machine contains ca. 50 wt % water. It is dried in dryer drums indirectly heated by burning tail gas. Dryer drums with a capacity of 2000 kg of carbon black per hour are 15 – 20 m long and 2 – 3 m in diameter. They are rotated at 5 – 15 rpm. Drying temperatures, generally between 150 and 250 °C, allow further modification of the carbon black properties.

The dried carbon black is transported via conveyor belts and elevators to the storage tank or packing station. Bulk densities of wet-pelletized carbon blacks are between 250 and 500 g/L.

A flow diagram summarizing the complete furnace black process is shown in Figure 61.

Figure 61. Furnace black process

6.4.2. *Gas Black and Channel Black Processes*

The channel black process, used in the United States since the late 1800s, is the oldest process for producing small-particle-size carbon blacks on an industrial scale. Originally, the first reinforcing blacks were also produced by this process. In 1961, world production of channel black was about 120 000 t. Due to low profitability and environmental difficulties, the last production plant in the United States was closed in 1976. Natural gas was used as the feedstock. The carbon black yield was only 3 – 6 %.

In Germany, where natural gas was not available in sufficient amounts, the gas black process was developed in the 1930s. It is similar to the channel black process, but uses coal tar oils instead of natural gas. Yields and production rates are much higher with oil-based feedstock; this process is still used to manufacture high-quality pigment blacks with properties comparable to those of channel blacks. The gas black process has been used by Degussa on an industrial scale since 1935.

Originally, gas black was primarily used for the reinforcement of rubber. Today, almost all grades are used as color blacks in printing inks, plastics, lacquers, and coatings. High-quality oxidized gas blacks are of special interest, e.g., in deep black lacquers and coatings.

In the gas black process (Fig. 62), the feedstock is partially vaporized. The residual oil is continuously withdrawn. The oil vapor is transported to the production apparatus by a combustible carrier gas (e.g., hydrogen, coke oven gas, or methane). Air may be added to the oil – gas mixture for the manufacture of very small particle size carbon black. Although this process is not as flexible as the furnace black process, various grades of gas black can be made by varying the relative amounts of carrier gas, oil, and air. The carbon black properties are also influenced by the type of burners used.

Figure 62. Degussa gas black process

a) Oil evaporator; b) Burner; c) Cooling drum; d (Bag filter; e) Blower; f) Rotary valve; g) Conveying screw

A gas black apparatus consists of a burner pipe approximately 5 m long, which carries 30 – 50 diffusion burners. The flames burn in contact with a water-cooled drum, where about half of the carbon black formed is deposited. This black is continuously scraped off and transported by a screw to a pneumatic conveying system. The gas black apparatus is surrounded by a steel housing open at the bottom. At the top, fans extract the off-gas into filters, which collect the carbon black suspended in the gas. The amount of air entering the apparatus can be regulated by valves in the exhaust pipes.

Several gas black apparatus are combined to form one production unit. The whole “group” is fed by one oil vaporizer. The production rate and the yield of an apparatus depend on the grade of carbon black produced. For a typical RCC black, the production rate is 7 – 9 kg/h and the yield is 60 %. The yield for high-quality color blacks is considerably lower (10 – 30 %).

To remove possible impurities, the gas black is classified and then densified, pelletized, or submitted to an oxidative aftertreatment (see Section Oxidative Aftertreatment of Carbon Black), depending on its intended use. Since gas blacks are formed in the presence of excess air, their surface is oxidized. Acidic surface oxides are predominant.

6.4.3. *Lamp Black Process*

The lamp black process is the oldest industrial-scale production process [420], [429].

Currently, only a few plants still produce rather coarse blacks (mean particle diameter ca. 100 nm) with special properties. They are used as nonreinforcing or semireinforcing blacks in rubber goods and as tinting black with a low pigment separation tendency.

The lamp black process is only partially continuous. The feedstock — oil with a high aromatic hydrocarbon content — is burned in flat steel vessels up to 1.5 m in diameter (Fig. 63). The oil is continuously introduced into the vessel to keep a constant feedstock level. The off-gas containing carbon black is sucked into a conical exhaust pipe, which is coated with a ceramic inner liner and leads to the cooling and collecting system. The properties of the carbon black can be influenced to some extent by variation of the distance between the vessel and the exhaust and the amount of air sucked into the apparatus. One lamp black apparatus can produce 100 kg/h. The production process must be interrupted at certain time intervals to remove coke-containing residues from the vessels.

Figure 63. Lamp black process

a) Vessel filled with feedstock; b) Conical exhaust pipe; c) Pipe leading to the collecting system

6.4.4. *Thermal Black Process*

Some special processes for producing carbon black are based on the thermal decomposition of lower gaseous hydrocarbons in the absence of air.

The thermal black process, which was developed in the 1930s, is still used for the production of coarse carbon blacks (nonreinforcing carbon blacks) for special applications in the rubber industry. Contrary to the above described processes, energy generation and the pyrolysis reaction are not carried out simultaneously.

A thermal black plant consists of two furnaces, which are used in alternate heating and production periods of ca. 5-min duration (Fig. 64). Each of the cylindrical furnaces (4 m in diameter and 6 m high) contains a network of heat-resistant bricks. They are heated with natural gas and air. At a temperature of ca. 1400 °C, the air is switched off and only feedstock is introduced for pyrolysis. Since this reaction is endothermic, the temperature falls. At about 900 °C, a new heating period is necessary.

Figure 64. Thermal black process

a) Thermal black reactor; b) Cooler; c) Filler bricks; d) Inlet for the feedstock; e) Inlet for the fuel; f) Outlet for the burned fuel; g) Outlet for the pyrolysis products; h) Carbon black outlet; i) Blower

The products leaving the furnace, carbon black and nearly pure hydrogen, are cooled by injecting water into an ascending channel. The carbon black is separated in the collecting system.

Carbon blacks of lower particle size can be produced by diluting the natural gas with recycled hydrogen. Fine thermal blacks (FT blacks) with mean primary particle sizes of 120 – 200 nm were manufactured in this way in the past. Medium thermal blacks (MT blacks) with mean particle sizes of 300 – 500 nm are still produced and are obtained by using undiluted feedstock. The yield of MT blacks is about 40 % with respect to the total amount of feedstock and fuel used.

Thermal blacks are used for mechanical rubber goods with high filler contents. Cheaper products (clays, milled coals, and cokes), however, have become increasingly important as substitutes for economic reasons. The total production of thermal blacks is, therefore, decreasing.

6.4.5. *Acetylene Black Process*

Acetylene and mixtures of acetylene with light hydrocarbons are the raw materials for a process that has been used since the early 1900s. Unlike other hydrocarbons, the decomposition of acetylene is highly exothermic (ΔH = – 230 kJ/mol).

The discontinuous explosion process is the oldest technical process. It was mainly used for the production of color blacks. Continuous processes were later developed with production rates up to 500 kg/h [432]. Acetylene or acetylene-containing gases are fed into a preheated, cylindrical reactor with a ceramic inner liner. Once ignited, the reaction is maintained by the decomposition heat that is evolved. The carbon black is collected in settling chambers and cyclones. Approximately 95 – 99 % of the theoretical yield is obtained.

The primary particles of acetylene black have different shapes than those of other carbon blacks (Fig. 65). As the increased order in the *c* direction of the crystalline regions indicates, folded sheets of carbon layers are the main structural component. Because of their relatively high price, the application of acetylene blacks is limited to special uses, e.g., in dry cells,. Total worldwide production is ca. 40 000 t/a.

Figure 65. Electron micrograph of acetylene black

6.4.6. *Other Manufacturing Processes*

In a plasma, hydrocarbon vapors may be almost quantitatively decomposed into carbon and hydrogen [433]. Many producers of carbon black have done research in this field. According to numerous patent specifications, this method can be used to make small-particle carbon blacks with new properties. However, an economical plasma-based commercial process is not yet known.

The Hüls electric arc process was the only large-scale process using plasma reactions in which large quantities of carbon black were produced as a byproduct of the production of acetylene. The particles of the Hüls arc carbon black resemble those of acetylene black. The mean primary particle size is ca. 35 nm. Today, this kind of carbon black is no longer used as a pigment.

Since the price of both feedstocks and fuels, and thus, the profitability of the carbon black production processes, is highly dependent on the petrochemical industry, several attempts have been made to find new raw materials. Processes for obtaining carbon black directly from coal [434] or for isolating carbon black from used tires, for example, have been studied. None of them, however, has been of any commercial importance up to now. On the other hand, clay, milled coal, and coke have found limited use as substitutes for very coarse carbon blacks, primarily thermal blacks and some SRF blacks. The increasing use of precipitated silicas in tires and mechanical rubber goods, mostly in combination with organosilane coupling agents, which originally was indicative of an increasing search for new non-oil-based fillers, has led to new rubber properties.

6.4.7. *Oxidative Aftertreatment of Carbon Black (Fig. 66)*

Oxygen-containing functional groups on the surface of carbon blacks strongly influence their application properties. High contents of volatiles, i.e., high concentrations of surface oxides, decrease the vulcanization rate and improve the flow characteristics of inks. The gloss of lacquers and coatings is increased, the color tone is shifted from brownish to bluish, and jetness often increases.

Figure 66. Equipment for the oxidative aftertreatment of carbon black in a fluidized bed

a) Fluidizing vessel; b) Reaction vessel; c) Desorption vessel

Due to the production conditions, only gas blacks (and channel blacks) are covered to a certain extent with acidic surface oxides. Furnace blacks contain only small amounts of oxygen in the form of basic surface oxides.

To amend their color properties, some color blacks are aftertreated by oxidation on a commercial scale. Depending on the oxidizing agent and the reaction conditions selected, different types of surface oxides are formed in varying quantities.

The simplest method of oxidizing the carbon black surface is by aftertreating it with air at 350 – 700 °C. However, the degree of oxidation is limited. Higher contents of surface oxides and better process control are achieved with nitric acid [435], mixtures of NO_2 and air [436], ozone, or sodium hypochlorite solutions [437] as oxidizing agents. As a rule, all strongly oxidizing agents may be used, either as a gas or in solution. Most surface oxidations of carbon black are carried out at elevated temperatures.

Oxidized carbon blacks may contain up to 15 wt % oxygen. They are strongly hydrophilic. Some of them form colloidal solutions spontaneously in water. In polar printing ink systems, lacquers, and coatings, a better wettability and dispersibility is achieved through surface oxidation [438], thus reducing binder consumption.

Surface oxidation of carbon black with nitric oxide and air can be carried out industrially in a fluidized-bed reactor [436]. A suitable aftertreatment unit consists of a preheating vessel, in which the carbon black is fluidized and heated, a reaction vessel to carry out the surface oxidation, and a desorption vessel, in which adsorbed nitric oxide is removed. Typical reaction temperatures lie between 200 and 300 °C. Depending on the degree of oxidation, the residence time can amount to several hours. The nitric oxide acts primarily as a catalyst, the oxygen in the air being the genuine oxidizing agent.

Oxidation of powdery black with ozone is also carried out on a commercial scale. Another common method of surface oxidation was carried out during pelletization. Instead of water, nitric acid was used as pelletizing agent. The surface was oxidized while the wet beads were dried at elevated temperature [439].

6.4.8. *Environmental Problems*

The furnace black process, the most economical and commercially advanced production method for carbon black, does not form toxic solid or liquid byproducts under normal operating conditions. The tail gas containing hydrogen and carbon monoxide was formerly emitted into the atmosphere, but is now burned, the energy being used partially within the process itself, e.g., for heating dryer drums in the wet-pelletizing process and for generating steam or electricity, so that emissions of carbon black and inflammable gases are avoided.

Although their economic importance is decreasing, progress with respect to environmental problems has also been made for the older processes that are still in use.

6.5. Testing and Analysis

The chemical composition of carbon blacks (see Section Chemical Properties), as determined by common elemental analysis methods, is of little significance for predicting their properties. Special characteristic properties are, therefore, determined for the characterization and quality control of carbon blacks. Traces of heavy metals are determined spectroscopically in the ash. Copper and manganese ions, etc., are of special interest to the rubber industry because of their interference with the aging process in rubber goods.

Electron Microscopy. Electron microscopy is one of the most important physical methods for the characterization of finely divided solids. It allows direct viewing of the shape and morphology of particles in this order of magnitude, primary particle size, particle size distribution, and aggregation.

To determine the mean primary particle size and particle size distribution, the diameters of 3000 – 5000 particles are measured on electron micrographs of known magnification. Spherical shape is anticipated for calculations. However, since the primary particles generally build up larger aggregates, the results may be somewhat uncertain. The specific “electron microscopic surface area” can be calculated from the primary particle size distribution. This value refers only to the outer (geometrical) surface of the particles. For porous carbon blacks the electron microscopic surface area is lower than the specific surface area according to BET (see below).

An attempt was made to find characteristic values for the type and degree of aggregation using electron micrographs [440]. However, neither visual comparisons with standard aggregates nor automatic picture analyses have led to a practical method for a quantitative characterization of the carbon black structure on a routine basis.

High-resolution phase-contrast pictures and X-ray diffraction are used to elucidate the internal structure of single primary particles.

Sorption Analysis. Specific surface areas and porosity can be calculated from the adsorption isotherm of nitrogen at – 196 °C. The BET method [441] is generally accepted for the evaluation of specific surface area (m^2/g). The two-parameter equation is applicable to carbon black. The BET surface area comprises the outer surface area as well as the surface area of

the pores. The outer surface area can be calculated from the adsorption isotherm by using the de Boer t-plot method.

Porosity of carbon blacks can be detected by the de Boer *t*-plot method [442]. The total surface area and the geometrical surface area outside the pores can be determined separately. Special attention must be paid to the selection of a suitable master *t* curve. Due to the small diameters of most carbon black primary particles, methods for the determination of mesopores are of no importance.

Special Analytical Test Methods. Test methods which on the one hand resemble certain physicochemical methods, but on the other hand already give some indication of application properties are summarized as special analytical test methods in Table 24. They can be carried out within a short time and are used for characterization as well as production control. Since the results are influenced by the test conditions, these test methods are standardized.

Table 24. Special analytical test methods for carbon black

Test method	Unit	Standard	Remark
Iodine adsorption	mg/g	ASTM D 1510; ISO 1304	amount of iodine adsorbed from aqueous solution as a measure for the specific surface area; not applicable for oxidized carbon blacks
CTAB surface area	m^2/g	ASTM D 3765; ISO 6810	amount of cetyl triammonium bromide adsorbed from aqueous solution as a measure for the specific outer surface area
BET surface area	m^2/g	ASTM D 3037; DIN 66 131, 66 132	total specific surface area calculated from the nitrogen adsorption isotherm by using the BET equation
External surface area	m^2/g	ASTM D 5816	STSA (statistical thickness surface area) calculated from the nitrogen adsorption isotherm
Aggregate dimension		ASTM D 3849	determination of aggregate dimensions (unit length, width, etc.) by electron microscope image analysis
DBP absorption	mL/100 g	ASTM D 2414; ISO 4656; DIN 53 601	determination of the wetting point with dibutyl phthalate in a special kneader as a measure for the carbon black structure
24M4-DBP absorption	mL/100 g	ASTM D 3493; ISO 6894	determination of DBP absorption after repeated compressing at high pressure as a measure for the permanent structure
Oil absorption	%	DIN ISO 787/5	percentage of linseed oil needed to make a barely flowable paste
Jetness, blackness value		DIN 55 979	light absorption of a carbon black paste in linseed oil; determination by visual comparison against standard blacks or by measuring the absolute light remission (DIN)
Tinting strength	%	ASTM D 3265; DIN ISO 787/16, 24; DIN 53 204; DIN 53 234	ability of a carbon black to darken a white pigment in a linseed oil paste; the tinting strength is the weight percentage of the standard carbon black with respect to the tested black to obtain the same gray tone; different standard white pigments and carbon black concentrations are used according to ASTM and DIN ISO
Volatiles	%	ISO 1126; DIN 53 552	weight loss when calcined at 950 °C for 7 min
Heating loss (moisture)	%	ASTM D 1509; DIN ISO 787/2	weight loss on drying at 125 °C for 1 h (ASTM) or 2 h at 105 °C (DIN ISO)
pH		ASTM D 1512; DIN 53 200	pH of an aqueous slurry of carbon black; pH is mainly influenced by surface oxides

Extractables	%	DIN 53 553	amount of extractable material (usually by boiling toluene) in at least 8 h
Toluene discoloration		ASTM D 1618; ISO 3858	light absorption (transmission) of a toluene solution of the extracted material
Ash content	%	ASTM D 1506; DIN 53 586	amount of noncombustible material after burning the carbon black at 675 °C (DIN) or 550 °C (ASTM, DIN)
Sulfur content	%	ASTM D 1619; DIN 53 584	
Sieve residue	%	ASTM D 1514; DIN ISO 787/18	amount of coarse impurities that cannot be purged through a testing sieve by water
Pour density	g/L	ASTM D 1513; DIN 53 912	measure for the densification of carbon black
Tamped density	g/L	DIN ISO 787/11	similar to bulk density; however, void volume is reduced by tamping
Pellet size distribution		ASTM D 1511	determination by means of sieve shaker
Fines content	%	ASTM D 1508; DIN 53 583	only for pelletized blacks; percentage passing through a sieve of 125 µm mesh width
Pellet crush strength	g	ASTM D 5230; ASTM D 3313	individual pellet hardness

Application Tests. Physicochemical and special analytical test methods allow the classification of carbon blacks and a rough estimation of their application properties. Exact data on the application properties of a carbon black in a special system, e.g., plastic material or a rubber mixture, can only be given by application tests under nearly practical conditions.

6.6. Storage and Transportation

The majority of the carbon black produced (up to 80 %) is transported as bulk material; the rest is handled in bags. Generally, the large stocks of pelletized furnace blacks for the rubber industry are stored, by the producers as well as the customer, in coated steel storage tanks consisting of one or more cells with a capacity of 100 – 1000 t (300 – 3000 m^3). Carbon black is shipped in containers or silo trucks with a capacity of up to 20 t. Recently, big bags and steel bins with a capacity of up to about 1 t have gained in importance. Smaller amounts of rubber blacks and especially pigment blacks are stored and transported in paper or plastic bags stacked on palettes. In some cases, bags with special coatings are used.

6.7. Uses

The most important grades and groups of carbon black, some typical characteristics, and the principal applications are summarized in Tables 25 and 26. A general overview of the most important application fields is given in Figure 67.

Table 25. Rubber blacks

ASTM No.	Iodine adsorption, mg/g	DBP absorption, mL/100 g	Use in natural and synthetic rubber
N 115	160	113	tire treads, rubber goods with high abrasion resistance (also as blend with N 220 and N 330 and N 326)
N 121	121	132	tire treads for high-performance passenger cars
N 125	117	104	tire treads for trucks, off-road tires
N 220	121	114	tire treads for trucks, tank pads, conveyor-belt covers
N 234	120	125	tire treads for high-performance cars, tank pads, conveyor belt covers
N 326	82	72	tire carcasses, steel cord adhesion compounds, mechanical rubber goods

N 330	82	102	tire treads, tire carcasses (blended with less-active carbon blacks), tire sidewalls, mechanical rubber goods
N 335	92	110	tire treads for passenger cars
N 339	90	120	tire treads for passenger cars, abrasion-resistant mechanical rubber goods
N 347	90	124	tire treads for passenger cars, abrasion-resistant mechanical rubber goods
N 351	86	120	tire treads, abrasion-resistant mechanical rubber goods
N 356	92	154	tire treads, cushion gum
N 375	90	114	tire treads for passenger cars and trucks, tank pads, conveyor-belt covers
N 539	43	111	tire carcasses, mechanical rubber goods with good dynamic properties, extrusion compounds
N 550	43	121	tire carcasses, mechanical rubber goods with good dynamic properties, extrusion compounds
N 650	36	122	tire carcasses, extrusion compounds
N 660	36	90	tire carcasses, molded goods
N 683	35	133	tire carcasses, tire sidewalls, mechanical rubber goods with good dynamic properties, extrusion compounds

Figure 67. Mean particle sizes and typical applications of various carbon blacks

About 90 % of the carbon black produced is used by the rubber industry as a reinforcing filler in tires, tubes, conveyor belts, cables, rubber profiles, and other mechanical rubber goods. Furnace blacks are predominantly used in rubber processing. Fine-particle-size carbon blacks (reinforcing blacks) are used for the production of rubber mixtures with high abrasion resistance (e.g., tire treads). Coarser carbon blacks (semireinforcing blacks) are used in rubber mixtures requiring low heat buildup during dynamic stress (e.g., carcass mixtures). Very coarse carbon blacks (nonreinforcing blacks) are incorporated into mixtures with high elasticity and good extrusion properties.

Table 25 lists furnace rubber blacks and their main application fields.

According to the commonly used ASTM classification (ASTM D 1765 and D 2516), rubber blacks are characterized by one letter and a three-digit number. The letter indicates the influence of the carbon black on the vulcanization process (N = normal curing, and S = slow curing). The first digit of the number should characterize the primary particle size or the specific surface area (Table 27). The other two digits are free and are used to identify individual grades within the group. Within each carbon black group, considerable variation in the combination of properties is possible, e.g., by varying the carbon black structure (DBP absorption) and surface activity.

Table 27. Classification of rubber blacks according to ASTM D 1765 and ASTM D 2516

Group no. (first digit of the three-digit ASTM number)	Average particle size, nm	Specific surface area*, m^2/g
0	1 – 10	>155
1	11 – 19	125 – 155
2	20 – 25	110 – 140
3	26 – 30	70 – 90
4	31 – 39	43 – 69
5	40 – 48	36 – 52
6	49 – 60	26 – 42
7	61 – 100	17 – 33
8	101 – 200	–
9	201 – 500	–

* The ranges of the specific surface area may vary, depending on the structure of the carbon blacks.

Quantitatively, the pigment blacks are substantially less important than the rubber blacks. They are used for the manufacture of printing inks, coloring plastics, fibers, lacquers, coatings, and paper (see Table 26). Oxidized carbon blacks are frequently used in the printing ink and coating industry. While high-color gas blacks are still predominant in lacquers and coatings, furnace blacks are becoming more and more important in plastics, coatings, and printing inks.

Besides their two main uses as reinforcing fillers and pigments, small amounts of carbon blacks are used by the electrical industry to manufacture dry cells, electrodes, and carbon brushes. Special blacks are used to give plastics antistatic or

electrical conduction properties. Another application is the UV stabilization of polyolefins [444].

6.8. Economic Aspects

In 1995, approximately (6 – 6.5)×10^6 t of carbon black was produced, and production capacity was estimated to be nearly 8×10^6 t/a (Table 28). The annual growth rate, on the average 7.9 % per annum between 1965 and 1975 in the United States, has since decreased substantially, primarily for rubber blacks due to longer tire life and the fact that the car market is reaching saturation. Therefore, the future growth rate of the carbon black market is expected to be rather limited and will not exceed 1 – 2 % per annum.

Table 28. Carbon black production capacity (1996)

Country or region	Capacity, 10^3 t
North America	1815
Western Europe	1310
Eastern Europe	1545
Asia	2630
South America	480
Africa, Australia	185
Total	**7965**

Nearly 40 % of the total world production capacity for carbon black is concentrated in the United States and Western Europe. A detailed survey of the capacities in Western Europe is given in Table 29.

Table 29. Carbon black production capacity in Europe (1995/96)

Country	Capacity, 10^3 t
United Kingdom	180
Germany	277
France	280
Italy	200
Netherlands	160
Spain	90
Sweden	40
Others	83
Total	**1310**

More than 90 % of the total amount of carbon blacks produced are used as reinforcing fillers in rubber, of which 65 – 70 % go into the tire industry and an additional 25 – 30 % are needed for the production of mechanical rubber goods. Less than 10 % of all carbon blacks produced are used for nonrubber purposes.

6.9. Toxicology and Occupational Health

As far as toxicology is concerned, one must distinguish between soot, which is formed by the uncontrolled combustion of coal and oil, and carbon black, which is industrially produced under precisely defined conditions. Commercial carbon blacks are characterized by an atomic ratio H : C of < 0.1, low ash content, and high adsorption capacity. The soluble organic fraction (extractable materials) is less than 0.5 wt %.

The “chimney-sweep cancer” described by P. POTT in England as early as 1775, which is basically related to soot but not to carbon black, was the starting point of intensive research on analytical test methods for polycyclic aromatic hydrocarbons (PAH) in carbon blacks. Increasingly refined test methods have been developed (e.g., column, thin-layer, and paper chromatography, gas chromatography, HPLC, UV and fluorescence spectrophotometry, and mass spectroscopy) to detect traces of such substances and to investigate the ability of carbon black surfaces to adsorb and to desorb PAHs.

Many years of experience in the carbon black producing and processing industry have clearly shown that there is no health hazard attributable to this product. Occasional allegations that carbon blacks impair human health have been refuted. In most cases it was possible to attribute these claims to confusion between carbon blacks and soot or coal dust. Carbon black differs markedly from soot, the unwanted, uncontrolled byproduct of combustion found in chimneys and the ambient air [445], [446].

Commercial carbon blacks (not aftertreated) consist of more than 95 % of carbon, and small amounts of hydrogen, oxygen and sulfur. They have an atomic ratio H:C of < 0.1 and a low ash content. In most carbon blacks the total toluene-extractable matter is less than 0.15 %, only part of which consists of polycyclic aromatic hydrocarbons (PAHs). Due to this low content and the highly adsorbent properties of carbon black, the extractable matter is bound very tightly on the surface and can only be removed with powerful solvents [447]. In contrast, soots vary widely in composition and properties. Besides carbon they contain variable amounts of inorganic and organic byproducts. Because of their uncontrolled genesis the content of extractable matter is often very high (> 25 %) and consists, among others, of a wide range of PAHs. The high content and loose binding of the PAHs is to a large extent responsible for the mutagenicity and carcinogenicity of soots.

Detailed studies of workers in the carbon black industry and among carbon black consumers in the United States and Europe have shown that carbon black causes neither structural damage to the lungs nor lung tumors. No association between cumulative carbon black exposure and the incidence of respiratory disease could be detected [448-450].

In small-animal tests no irritation of the mucous membranes or eyes was observed. Also no changes could be detected when the skin was exposed to carbon black. Conversely, animals exposed to the benzene extract of the same carbon black developed a significant number of malignant tumors [451]. If adsorbed on the carbon black surface, the PAHs are biologically inactive. Tests in five systems for genetic activity of a furnace black containing 294 ppm toluene-extractable PNAs indicated that no mutagenic activity could be attributed to whole carbon black [452]. The results of several studies provided no indications of pathological effects in the gastrointestinal tracts when carbon blacks were ingested in rodents [453].

Harmful materials other than PAHs, such as polychlorinated bi- and triphenols, polychlorinated dioxins, and polychlorinated hydrofurans, were not found in carbon blacks. Nitrosamines could not be detected in carbon black, but they may be formed in rubber compounds if rubber chemicals containing secondary amines are used. The total amine content of carbon black is less than 0.01 %, and the aromatic amine content is therefore even lower. Heavy metal content does not exceed 0.002 %. Carbon blacks therefore conform to all known regulations that limit these impurities.

Lifelong inhalation studies on various species, involving titanium dioxide, iron oxide, talc, diesel soot, as well as carbon black, have shown that these fine dusts, hitherto regarded as inert are toxic to the lung [454], [455]. Of the various species used in the studies, including rats, mice and hamsters, only the rat developed identifiable lung tumors. In all cases the rats were exposed to high dust levels for prolonged periods of time, to the point that they experienced a phenomenon termed “lung overload“. The effect is not restricted to carbon black. It appears from the results of long-term inhalation studies that any insoluble, low-toxicity particle will cause lung tumors in rats if deposited chronically at high enough doses [456]. Extrapolating the incidence of lung tumors in rats inhaling inert insoluble particles, such as carbon black, to human responses must be seriously questioned. The tests were carried out under such extreme overload conditions, never experienced in the workplace today, that the lungs of the rats were unable to clear themselves during nonexposure periods.

Such high carbon black levels could not occur in modern carbon black production plants. Most of the carbon black producing countries have adopted the U.S. TLV of 3.5 mg/m^3 [457]. Extensive sampling in a number of carbon black plants in Europe [458] resulted in an occupational exposure standard (OES) for carbon black of 3.5 mg/m^3 (8-h TWA) and 7 mg/m^3 (STEL). In an exhaustive review in 1984, carbon black was classified by IARC [459] in Group 3: *Not classifiable as to its carcinogenicity to humans*. This classification was confirmed in 1987. However, based on the results of the inhalation studies with rats, IARC [460] reclassified carbon black in 1995 in Group 2B: *The agent is possibly carcinogenic to humans*. The criteria applied are: Inadequate evidence in humans and sufficient evidence in experimental animals.

Only if strong evidence can be provided that the mechanism of carcinogenicity in rats does not operate in humans might a new reclassification of carbon black by IARC in Group 3 be possible.

Food Contact Regulations. Carbon blacks, which according to their application properties may be used for food products, cosmetics, drinking water pipes, food packaging materials, and toys, must comply with local regulations. The testing methods for the approval of carbon blacks for such applications are different in different countries. The general aim, however, is to give limitations for the content of PAHs and of heavy metals. In general, the amount of heavy metals is far below the limitations. With respect to PAHs, either the total amount of extractable materials or the content of special species is limited. Since industrial carbon blacks contain only trace amounts of strongly adsorbed PAHs, the majority of commercial grades comply with these regulations.

7. Fullerenes

Otto Vostrowsky and Andreas Hirsch

7.1. History

It has been known since the early work of HAHN et al. on nuclear fission products [461] that in the gas phase at 3000 – 4000 °C under the conditions of a high-frequency arc carbon tends to form C_n clusters. Cluster ions up to C_{15} were detected [462]. In 1970 OSAWA recognized that the bowl-shaped corannulene **1** is part of a soccer-ball framework, and postulated the existence of the stable C_{60} cluster **2** [463] and discussed its possible aromatic properties [464].

1 **2**

In 1984 it was observed that upon laser vaporization of graphite, large all-carbon clusters C_n with n = 30 – 190 can be produced [465]. Only ions with even numbers of carbon atoms were observed in the mass spectra of these carbon clusters, among which were C_{60} and C_{70}. Their identity, however, was not recognized at this time. The breakthrough came in 1985 [466] when KROTO visited the Rice University in Houston, where SMALLEY and coworkers had developed a technique [467] for generating clusters by focusing a pulsed laser on a solid (in this case graphite) and studying them by mass spectrometry. The original goal of KROTO and SMALLEY was to simulate the conditions under which carbon nucleates in red-giant stars. Under specific conditions of cluster formation, a peak attributed to C_{60} (m/z = 720) and a less intense peak attributed to C_{70} (m/z = 840) exhibit pronounced intensity in the spectra. Conditions were found under which the mass spectra were completely dominated by the C_{60} signal. KROTO and SMALLEY concluded that the stability of C_{60} is due to its spherical structure, that is, a truncated icosahedron with I_h symmetry (Fig. 68). The substance was named buckminsterfullerene due to its geometrical similarity with the geodesic domes constructed by the American architect BUCKMINSTER FULLER and its discovery was reported to *Nature* on September 12, 1985 [466]. Later the enhanced intensity of the peak for C_{70}, another stable fullerene, was understood. Although buckminsterfullerene C_{60} had been discovered, a method for its synthesis in macroscopic amounts remained to be found.

Figure 68. Ball-and-stick model of buckminsterfullerene

The second breakthrough in the fullerene research was achieved by KRÄTSCHMER and HUFFMAN [468]. Their intention was to produce laboratory analogues of interstellar dust by vaporization of graphite electrodes in a helium atmosphere [469]. At a certain helium pressure, the IR spectra of the soot generated by the vaporization of graphite showed four sharp absorptions besides the continuum of regular soot [470]. These absorptions were close to the positions predicted for buckminsterfullerene [471]. The fullerenes were isolated from the soot by sublimation or extraction. This allowed the determination of spectroscopic and crystallographic data, as well as experiments with ^{13}C-enriched material, and moved C_{60} from the world of elusive objects known only from mass spectroscopy to that of material science. Higher fullerenes can also be obtained in appreciable amounts by this technique.

The discovery of C_{60} led to an explosive growth in research into the properties of this new class of carbon allotropes. More than a thousand publications on fullerenes appear each year, dealing with their chemical and physical properties and material science aspects.

The discovery of the fullerenes was honored by the award of the Nobel prize for Chemistry in 1996 to KROTO, CURL, and SMALLEY.

7.2. Production

7.2.1. *Vaporization of Graphite*

Resistive Heating of Graphite. The resistive heating of graphite was the first method for producing macroscopic quantities of fullerenes [468]. The apparatus first used by KRÄTSCHMER et al. for the production of C_{60} was a bell jar connected to a pump and gas inlet. In the jar two graphite rods — one sharpened to a conical point and the other with a flat end — are kept in contact by a spring. The apparatus is evacuated, filled with 140 mbar of helium, and an electric current passed through the rods. This heats the point of contact to 2500 – 3000 °C and forms a black smoke, which condenses on the bell jar and a smoke catcher. The fullerenes are extracted from the soot with toluene in a yield of 10 – 15 %. The HUFFMAN – KRÄTSCHMER process has been patented, and the first computer-controlled, fully automated fullerene production systems are now commercially available.

More simply constructed modifications of this fullerene generator have been developed [472-474], in which vertical graphite electrodes are fed by gravity. This, together with low costs, make them more attractive to synthetic chemists. A simple benchtop reactor gives a yield of fullerenes based on evaporated graphite in the range of 5 – 10 % [474].

Arc Heating of Graphite. Arc vaporization [475-477] of graphite was first developed by SMALLEY [476]. The tips of two sharpened graphite rods are kept at contact-arcing distance [476], so that the electric power is dissipated in an electric arc rather than in ohmic heating. This method allows efficient evaporation of carbon; the yield of fullerenes is about 15 %. The

disadvantage of this method is the intense UV radiation originating from the arc plasma. The absorption of UV light by fullerenes produces a triplet state T_1 with a lifetime of a few microseconds [478]. In the T_1 state, the fullerene is an open-shell system that can readily react with other carbon species C_n to give a nonvaporizable insoluble product [476].

Solar Heating of Graphite. The problem of intense UV radiation is avoided by the use of solar furnaces as fullerene generators [476], [478], which lead to far lower exposure of the fullerenes to radiation than arc vaporization or resistive heating. In the solar generator developed by SMALLEY [476], sunlight is focused by parabolic mirrors onto the tip of a graphite rod under an argon atmosphere in a Pyrex tube. The condensing carbon vapor quickly moves away from the intensive sunlight, cools in the upper regions of the Pyrex tube, and subsequently deposits on the upper walls. Although fullerenes can be obtained in this way, the efficiency of the generator is not very high.

Inductive Heating of Graphite. Fullerenes can also be produced by direct inductive heating of a carbon sample in a boron nitride support [479]. Evaporations at 2700 °C in a helium atmosphere lead to the formation of a fullerene-containing soot, which can be collected on the cooler parts of the Pyrex reactor. This method allows continuous operation by keeping the graphite sample continuously in the heating zone. The evaporation of 1 g of graphite gives 80 – 120 mg of fullerene extract within 10 min.

7.2.2. *Fullerene Synthesis by Combustion*

The existence of fullerenes in sooty flames was first revealed by mass spectrometry [480], and the production of fullerenes in optimized sooty flames was shown to be feasible [481]. Premixed laminar benzene – oxygen – argon flames operated at different pressures, temperatures, and carbon to oxygen ratios have been used. Besides fullerenes and soot, polyaromatic hydrocarbons are formed. The yield of fullerenes and the C_{70}/C_{60} ratio strongly depend on the operating mode. The yield of C_{60} and C_{70} is in the range of 0.003 – 9 % of the soot mass. Expressed as percentage of fuel carbon, the yields vary from 2×10^{-4} to 0.3 %. The C_{70}/C_{60} ratio varies over the range 0.26 to 5.7, which is much larger than that observed for graphite-vaporization methods (0.02 – 0.18). This ratio tends to increase with increasing pressure.

7.2.3. *Pyrolysis of Naphthalene*

Fullerenes can also be obtained by pyrolysis of naphthalene at 1000 °C in an argon stream [482]. The naphthalene skeleton is a monomer of the C_{60} structure. The fullerenes are formed by dehydrogenative coupling reactions. Primary reaction products are polynaphthyls with up to seven naphthalene moieties. Full dehydrogenation leads to both C_{60} and C_{70} in yields less than 0.5 %. Hydrofullerenes such as $C_{60}H_{36}$ have been observed as side products by mass spectrometry.

7.3. Structure and Nomenclature

Fullerenes and fullerene-like nanostructures are defined as polyhedral cages made up entirely of five- and six-membered rings. The structural principle obeys Euler's theorem, which states that for the closure of a spherical network of N hexagons, twelve pentagons are required, with the exception of $N = 1$. Therefore, fullerenes contain $2(10 + N)$ carbon atoms. Hence, the smallest conceivable fullerene is C_{20}, and all fullerenes must contain an even number of carbon atoms. Since it is energetically unfavorable in unsaturated molecules for two pentagons to be adjacent to each other, the pentagons should be isolated by hexagons (*isolated pentagon rule* IPR [483]). For soccer-ball-shaped C_{60} only one IPR isomer is possible; it is the smallest stable fullerene. The rugby-ball-like C_{70} also has only one IPR isomer and is the next stable homologue, followed by the higher fullerenes C_{76}, C_{78}, C_{80}, C_{82}, C_{84}, C_{90}, and C_{96}. With increasing number of hexagons, the number of possible fullerene isomers rises dramatically. For C_{78}, five IPR isomers and more than 20 000 general isomers [484], [485] can be imagined. The number of strain-free fullerene isomers that are possible becomes considerably lower if only IPR structures are allowed. Taking into account that open-shell structures are avoided [485] and that the number of double bonds in pentagons are minimized [486], magic numbers n for stable fullerenes C_n can be predicted as n = 60, 70, 72, 76, 78, 84, . . . [485] (Fig. 69).

Figure 69. Ball-and-stick models of C_{70}, C_{76}, C_{78}, and C_{84}

C_{60} belongs to the highly symmetric point group I_h (120 symmetry operations). Many of the higher fullerenes are chiral, and the number of possible chiral isomers also increases with increasing cage size. Because of its D_2 symmetry, C_{76} exists in two enantiomeric forms. Two of the five possible IPR structures of C_{78} are chiral, as are ten of the 24 possible IPR structures of C_{84}. These carbon allotropes are rare examples for chiral modifications of pure elements.

Since the IUPAC names of the fullerenes are too lengthy and complicated for general use [487], simpler designations have been developed. For example C_{60} can be named [60-I_h]fullerene, which sufficiently describes its structure. The number 60 denotes the number of carbon atoms, and I_h the symmetry group. Since for C_{60} and C_{70} only one stable IPR isomer exists, their names simplify to [60]fullerene and [70]fullerene. The indication of the symmetry group, however, is important for higher fullerenes, for which different isomers coexist, e.g., [78-D_3]fullerene and [78-C_{2v}]fullerene.

7.4. Physical Properties

The *heat of formation* of [60]fullerene is 42.54 kJ/mol [488] and that of [70]fullerene 40.40 kJ/mol per C atom [489]. It is expected that upon increasing the size of the fullerenes their energy content will asymptotically reach that of graphite [488],

[490].

The *solubility* of [60]fullerene has been investigated systematically [491], [492]. It is essentially insoluble in polar solvents, and sparingly soluble in alkanes. In aromatic solvents and in carbon disulfide appreciable solubilities are observed. A significant increase of the solubility is observed in going from benzenes to naphthalenes. Curiously, its solubility passes through a maximum with increasing temperature [491]. The solubility (in mg/mL) of [60]fullerene in various solvents [491] is as follows:

n-Pentane	0.005
n-Hexane	0.043
Cyclohexane	0.036
n-Decane	0.071
Decalins	4.6
Dichloromethane	0.26
Carbon disulfide	7.9
Dichloromethane	0.26
Chloroform	0.16
Tetrachloromethane	0.32
Tetrahydrofuran	0.000
Benzene	1.7
Toluene	2.8
Tetralin	16
Benzonitrile	0.41
Anisole	5.6
Chlorobenzene	7.0
1,2-Dichlorobenzene	27
1-Methylnaphthalene	33
1-Chloronaphthalene	51
Acetone	0.001
Methanol	0.000

Fullerenes form solvates with many organic solvents. Slow crystallization of C_{60} from benzene gives the solvate $C_{60}(C_6H_6)_4$ [493]. Cocrystallates with ferrocene [494], bis(ethylenedithio)tetrathiafulvalene [495], $[Fe_4CO_4(\eta^5\text{-}C_5H_5)_4]$ [496] iodine [497], 1,4-hydroquinone [498], sulfur (S_8) [499], calixarene [500], and γ-cyclodextrin [501] have been characterized.

The *UV/VIS spectrum* [472] of [60]fullerene exhibits strong absorption bands at 213, 257 and 329 nm, as well as some forbidden transitions in the visible region of the spectrum, which are due to forbidden singlet – singlet transitions and are responsible for the purple color of solutions of [60]fullerene in toluene.

Solutions of [60]fullerene in hydrocarbon solvents are magenta, and those of [70]fullerene are port-wine red. In the same solvents, [76]fullerene gives yellow-green solutions, as does [84]fullerene; [82]fullerene has a less greenish tinge. Solutions of [78]fullerene are golden chestnut brown.

In the solid state, C_{60} molecules crystallize in a face-centered cubic (fcc) *crystal structure* [502] with a lattice constant of 1.417 nm. The density in the solid state is 1.72 g/cm^3 [468]. At 260 K, a first-order phase transition from the fcc to a simple cubic (sc) structure is observed [503], accompanied by a lattice contraction (lattice constant 1.410 nm). At 90 K the molecules rearrange to attain the best global minimum, that is a higher order phase transition. At this temperature, the rotational degrees of freedom are frozen, and the solid structure is designated as a pseudo-fcc structure (Fig. 70). [70] Fullerene is also rotationally disordered at room temperature and undergoes a transition to a low-temperature phase [504].

Figure 70. Phase transitions and variation with temperature of the cubic lattice constant of solid [60]fullerene

[60]Fullerene is an insulator but exhibits *electrical conductivity* when doped with electropositive metals. Crystalline phases have been obtained by exohedral doping with alkali and alkaline earth metals, in which the dopants enter the host crystal structure in interstitial lattice positions [505], [506]. The metal atoms are diffused into solid C_{60}, and donate electrons to C_{60} to form C_{60}^{n-} anions. A large variety of alkali metal fullerides M_nC_{60} have been synthesized and studied with respect to their physical and solid-state properties [507-512]. Alkali metal fullerides exhibit superconductivity [513]. The fulleride superconductors have the general formula M_3C_{60} and crystallize in a fcc lattice (except for Cs_3C_{60}), in which the three metal

ions are located in the two octahedral and the tetrahedral site between the spheres. The highest T_C was found for Cs_3C_{60} (40.0 K) [514], followed by $RbCs_2C_{60}$ and Rb_2CsC_{60} (33.0 K and 31.3 K, respectively) [515]. Na_3C_{60} is not superconducting, which is attributed to the fact that below 260 K a reversible structural transition leading to a two-phase mixture of Na_2C_{60} and Na_6C_{60} takes place [512].

Reaction of C_{60} with the organic donor TDAE [tetrakis(dimethylamino)ethylene] leads to the charge-transfer complex $[TDAE^+]C_{60}^-$, which has ferromagnetic properties [516], [517]. This compound exhibits the highest magnetic ordering temperature T_C = 16.1 K of organic molecular ferromagnets.

7.5. Chemical Properties

Reviews on the synthetic organic chemistry of fullerenes can be found in [518-522].

7.5.1. *Addition Reactions*

The additions of nucleophiles [518], [519], [523] and radicals [524] to the electrophilic [6,6] double bonds ([6,6] denotes the junction of two hexagons) are among the earliest observed reactions in fullerene chemistry. On addition of nucleophiles (Nu) the initially formed anionic intermediates $Nu_nC_{60}^{n-}$ can be stabilized by addition of electrophiles E^+ to give substituted fullerenes $C_{60}ENu$ or by an S_Ni reaction to give methanofullerenes. Suitable sources of carbon nucleophiles are Grignard or organolithium reagents RMgX and RLi, which form the anions RC_{60}^- to $R_nC_{60}^{n-}$ as primary intermediates [523], [525], [526]. Their protonation yields the hydrofullerene derivatives $C_{60}H_nR_n$ (Fig. 71). Highly alkylated anions $R_nC_{60}^{n-}$ have been quenched with MeI to form $C_{60}Me_nR_n$ [525]. The generation of carbon nucleophiles by deprotonation of α-halo esters or α-halo ketones in the presence of fullerenes leads to cyclopropanation [527]. Cyclopropanated fullerenes are also formed on treating of C_{60} with phosphonium ylides [528]. [60]Fullerene reacts readily with primary and secondary aliphatic amines [523], [529], but often complex mixtures of amino adducts are obtained. Isomerically pure mono adducts are obtained by the reaction of secondary diamines such as *N,N*-dimethylethylenediamine, piperazine, or homopiperazine with C_{60} [530] (Fig. 71).

Figure 71. Typical addition reactions of [60]fullerene

Like olefins, [60]fullerene undergoes many thermal, photochemical, and electron-transfer-activated cycloadditions. In [4 + 2] cycloadditions, the [6,6]-bonds of C_{60} act as dienophiles [518], [523], [531]. Methano-bridged fullerenes are accessible bycycloaddition of diazomethanes, diazoactates, and diazoamides to C_{60} [518], [523]. The reaction of azides with C_{60} gives aza-bridged fullerenes [532] (Fig. 71).

The addition of benzyne and electron-rich alkynes to [60]fullerene or the photopolymerization of C_{60} leads to [2 + 2]-cycloadducts [533]. [2 + 1]-Cycloadducts are formed by addition of carbenes or of silylenes to [60]fullerene [518], [522].

The facile nucleophilic addition of primary and secondary amines to C_{60} has been used to synthesize fullerene-based polymers and polymer-bound C_{60} [534]. Self-assembled monolayers of covalently bound C_{60} have been synthesized by treatment of C_{60} with $(MeO)_3Si(CH_2)_3$-modified iridium tin oxide surfaces [535] and cysteamine-modified gold surfaces [536].

The strongly electron withdrawing fullerenes behave like “radical sponges”. Radicals can readily add to [60]- and [70]fullerene to form fullerenyl radicals. Radicals in which up to 34 methyl groups are attached to the cage have been produced [529]. A number of alkyl-, benzyl-, phenyl-, and thiomethyl-substituted fullerenyl radicals have been obtained [529], [537]. The addition of radicals has been used to synthesize fullerene polymers and perfluoroalkylated fullerenes.

7.5.2. *Hydrogenation*

Dihydrofullerene $C_{60}H_2$ is synthesized by hydroboration [538], hydrozirconation [539], and zinc/acid reduction [540]. Of the 23 possible regioisomers, only the 1,2-adduct is formed. The soluble $[(\eta^5\text{-}C_5H_5)_2ZrClC_{60}H]$ complex obtained by hydrozirconation undergoes further hydrozirconation [539]. Hydrolysis of the higher adducts leads to $C_{60}H_4$ and $C_{60}H_6$ as mixtures of regioisomers. Hydroboration of [70]fullerene followed by hydrolysis gives two isomers of $C_{70}H_2$. Exhaustive hydrogeneration of C_{60} leads to mixtures of unstable polyhydrofullerenes $C_{60}H_{2n}$ [473], [541]. Attempts to synthesize the fully hydrogenated $C_{60}H_{60}$ have so far failed.

7.5.3. *Halogenation*

[60]Fullerene is fluorinated by XeF_2 [542] or fluorine gas [543] to give mixtures of polyfluorofullerenes $C_{60}F_{2n}$ (e.g., n = 15 – 22). A defined regioisomer of $C_{60}F_{48}$ was synthesized by reaction of solid C_{60} with fluorine gas in the presence of NaF

[544]. Higher degrees of fluorination are obtained by reacting perfluorinated fullerenes with fluorine under UV radiation [544]. The most extensively fluorinated species is $C_{60}F_{102}$, which requires rupture of the fullerene framework. Polychlorination of C_{60} can be achieved with chlorine gas at 250 – 400 °C [545] or liquid chlorine at – 35 °C [546]. The chlorofullerenes are less stable than their fluorine analogues. Treatment of [60]fullerene with liquid bromine gives the yellow-orange, crystalline $C_{60}Br_{24}$ [547]. Reaction of C_{60} with iodine occurs on irradiating a $C_{60} – I_2$ mixture at 130 °C to give $C_{60}I_2$ [548].

7.5.4. *Reduction*

Reductions were the first chemical transformations carried out with fullerenes. Electron transfer reactions with electropositive metals, and organic donor reagents, as well as electrochemical reductions have been used to prepare fulleride salts. The fulleride ions readily undergo subsequent reactions with electrophiles.

Fullerenes are readily reduced by alkali and alkaline earth metals. Thus, titration of a suspension of C_{60} in liquid ammonia with a solution of Rb in ammonia or ultrasound-aided treatment with Li metal in THF generates fullerides C_{60}^{n-} (n = 1 – 5 for Rb^+, n = 1 – 24 for Li^+). Defined compounds M_nC_{60} with M = Na, K, Rb, Cs and n = 2, 3, 4, and 6 [507-510] as well as mixed alkali compounds $M_n^1M_n^2C_{60}$ can be obtained [510]. Sodium and potassium fullerides can also be synthesized by solid-state reaction of C_{60} with NaH, KH, $NaBH_4$, or KBH_4 [549]. Other techniques apply vapor-transport procedures [550] or binary alloys [509] as the alkali metal source. A bulk reduction of C_{60} with the less electropositive mercury was also demonstrated [551].

Fulleride salts are also formed with organic or organometallic donor molecules. The reduction with donors like (tetraphenylporphinato)chromium(II), cobaltocene, bis(*N*-methylimidazole)(tetraphenylporphinato)tin(II), tetrakis (dimethylamino)ethylene (TDAE) or $[Fe^I(C_5H_5)(C_6Me_6)]$ leads to fullerene-based charge transfer complexes, some of which show remarkable electronic and magnetic properties [531], [552].

7.6. Endohedral Fullerenes

The hollow fullerene molecules are potential hosts for trapping smaller guest molecules in the spherical carbon cage. Such structures were first obtained with lanthanide guests and are usually referred to as endohedral fullerenes. Their discovery in 1985 stemmed from the observation of La-related peaks in the mass spectra of material that was obtained by laser vaporization of graphite soaked in $LaCl_3$ solution [553]. They were formulated as $La@C_{60}$ and $La_2@C_{60}$. (To assign the position of the metal with an appropriate nomenclature an “@” is added to the name, and endohedral heteroatoms are placed to the left of the @, whereas heteroatoms of the fullerene framework are positioned to the right of the @.)

Endohedral metal fullerene complexes are prepared by laser and arc vaporization of graphite impregnated with metal salts, metal oxides or carbides [554]. Among others, Li, K, Rb, Cs, Ca, Sc, Y, La, Ce, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Lu, U, Ti, Zr, Hf, Fe, and Co complexes can be prepared in this way, with various fullerene cage sizes. For the larger fullerenes, the endohedral addition of up to four metal ions has been demonstrated by mass spectrometry [555]. The interior of C_{82}, which is approximately 8 Å in diameter, can readily accommodate three rare earth trivalent ions [556].

Atoms of the noble gases He or Ne are incorporated inside C_{60} by arc vaporization of carbon electrodes in the presence of these gases [557]. The first helium compounds $He@C_n$ (n = 60, 70, 76, 78, 84) were prepared by heating fullerenes to 600 °C in a helium atmosphere at 3000 atm [558]. Also Ne, Ar, Kr, and Xe were successfully introduced into fullerenes [558] by heating under high-pressure or by the impact of high-energy ion or atom beams [559]. The endohedral fullerene $N@C_{60}$ [560] is produced by bombardment of C_{60} with N_2^+ and N^+ ions or in a glow discharge reactor [560].

7.7. Carbon Nanotubes and Nanostructures

In 1991 IIJIMA observed by high-resolution transmission electron microscopy the formation of multilayered *carbon nanotubes* on the surface of a carbon arc cathode [562]. These tubules, which consist of several coaxial tubes and a hollow core, have typical lengths of up to 1000 nm; the outer diameter ranges between 2 and 20 nm, and the inner diameter between 1 and 3 nm. The longest reported *carbon nanotube* length was 700 nm for a 0.9 nm diameter tubule [563]. The *multi-walled nanotubes* MWNT (“buckytubes”) can consist of 12 to 50 coaxial tubes, each of which is formally a graphite sheet rolled to a cylinder and closed at each end by a hemifullerene end cap (Fig. 72).

Figure 72. Singe-wall nanotube sealed at one end by a hemi-[60]fullerene cap

Carbon nanotubes have been generated by carbon arc discharge [562], [564], pyrolysis of hydrocarbons [565] or triazine over catalysts [566], carbon vapor deposition [567], condensed phase electrolysis [568], and carbon ion bombardment [569]. For the preparation of single-wall nanotubes, the carbon anode is modified by addition of a transition metal, which serves as a catalyst [570]. In 1996, an improved method for making single-wall nanotubes became available [571]; the tubes are obtained in bundles in about 50 % yield (cf. 1 % yield of soluble fullerene material). Instead of single tubes, ropes consisting of 10 – 100 parallel nanotubes are found. The smallest bundle is a microbundle consisting of 10 to 100 aligned nanotubes of almost equal length.

Carbon nanotubes are extremely strong; the Young's modulus of individual MWNTs is 0.4 – 3.7 TPa (experimental) [572], and a value of 5.5 TPa has been calculated [573] for MWNTs and SWNTs. Single-walled tubes are remarkably flexible and

bend into curved arcs with radii as small as 20 nm. Nanotubes bent to an angle of 30 ° develop kinks, but the hexagonal pattern remains intact up to 110 ° [574].

Carbon nanocones are found on the caps of nanotubes and also as free-standing structures generated in a carbon arc. Concentric hollow carbon spheres with onion-like structure [575] are formed upon intense electron beam irradiation of carbon particles, by shock-wave treatment of carbon soot, from carbon exposed to a plasma torch, by laser melting of carbon, and by annealing nanodiamonds at temperatures above 1000 °C. These *carbon onions* ("buckyonions") contain no dangling bonds and are remarkably stable. An innermost sphere with an inner diameter of 7.1 Å, corresponding to the diameter of the C_{60} molecule, was reported in one case.

7.8. Application Properties of Fullerenes

Solid fullerenes are compressible because of the weak van der Waals forces between the fullerene molecules in the lattice. Various high-pressure phases of C_{60} and C_{70} have been characterized [576]. When compressed to 70 percent of its original size, C_{60} becomes more than twice as hard as diamond. Thus, it could be applied as a shock absorber for high-energy collision or for reinforcing metals or plastics. Cross-linked polymers and high-performance polymer films can be obtained by cross-linking C_{60} with resins. These materials are very hard and thermally extremely stable.

In C_{60} – polymer composites, fast photoinduced electron transfer occurs from the polymer to the C_{60} molecule and photoconductivity is observed [577]. The efficiency of organic photoconductors could be improved by addition of C_{60} [577], [578]. This discovery may lead to applications in xerography, laser printers, fax machines.

Fullerene-based transistors have been constructed [579], and a variety of $M/C_{60}/M$ (M = metal) diodes and field effect transistors (FETs) proposed. Proposed application in the fabrication of microelectronics, include films for patterning, surfaces of uniform electric potential for electronic applications [580], passivation of surfaces [581], and adhesives for bonding silicon wafers [582].

The possibility of using C_{60} for hydrogen storage [583] might be useful not only in energy storage cells but also in high-energy-density primary batteries.

Investigations of the lubricating properties of fullerene films [584] showed that fullerenes may be of interest as high-temperature lubricants and anticorrosion coatings. The most important application of fullerenes in lubrication engineering is as additives in oils and greases [585]. By total fluorination of C_{60} a fully fluorinated "teflonball" $C_{60}F_{60}$ should be accessible which is assumed to represent the slickest molecular lubricant known to man. However, highly fluorinated C_{60} is unstable in the presence of traces of water [586].

1. Introduction

The existence of carbon dioxide has been known since primitive times [1]; PLINY wrote of lethal vapors from caverns in the first century A.D. [2]. It was first recognized as a distinct gas, however, by VAN HELMONT (1577 – 1644), who prepared the gas by various routes and demonstrated that it was the same gas as that which issued from caverns and mines [3]. He obtained it by fermentation, by the action of acids on carbonates, and by the burning of charcoal, and he studied many of its properties. Soon after, HOFFMANN, while investigating gas escaping from effervescent mineral waters, observed that the gas was acidic by its effect on blue vegetable coloring materials [4]. BLACK, in 1757, showed that during respiration part of the atmospheric air was chemically changed, and discovered the lethal effect such "fixed air" had on animal life [5]. CAVENDISH made various observations on the chemical properties of "fixed air" [6], and PRIESTLEY, who lived near a brewery, made further observations on the physical properties of the gas, finding that pressure favored dissolution of the gas in water [7]. The French chemist LAVOISIER was the first to prove the composition of "fixed air" by showing that it was produced when carbon is heated in oxygen [8]. The resultant gas, which he named carbonic acid, was found to contain 23.5 – 28.9 parts by mass carbon and 71.1 – 76.5 parts by mass oxygen [9].

The commercial exploitation of carbon dioxide began with attempts to produce artificial mineral waters (solutions of CO_2 in water), which were thought to have medicinal properties. The industrial development of the gas really began, however, with the experiments of FARADAY on the liquefaction of gases. He succeeded in liquefying CO_2 in a bent glass tube [10]. THILORIER repeated these experiments on a large scale [11]. Two iron retorts connected by a flexible

10.1002/14356007.a05_165

coupling were used; the first contained a reaction mixture of sodium hydrogen carbonate and sulfuric acid. This was agitated, and the carbon dioxide thus produced was liquefied under pressure in the second retort. Despite a spectacular explosion, which killed his assistant, THILORIER succeeded in carrying out extensive experiments on the expansion, vapor pressure, density, and enthalpy changes of the liquid CO_2 during evaporation. He was also the first experimenter to produce solid carbon dioxide, which, on the evaporation of liquid carbon dioxide, appeared as a white, flocculant, easily compressible mass. He observed that it disappeared by slow evaporation without first melting to form a liquid (i.e., it sublimed).

In 1845, FARADAY made larger quantities of liquid and solid carbon dioxide by means of a hydraulic pump [12]. He also used solid carbon dioxide, in a mixture with ether, as a refrigerant for use in further gas liquefaction studies. Soon after, NATTERER developed a mechanical compressor (a forerunner of the modern multistage type), which was used to make liquid carbon dioxide [13]. As uses for the new liquid were proposed, compressors were developed to produce greater quantities. The first factory for the production of liquid carbon dioxide was established by RAYDT in Germany in 1884, and the development of the industry continued as more uses were found [14]. In particular, its uses in ice-making and refrigeration and as a fire extinguisher became important. Much carbon dioxide issued from the earth naturally in places such as Germany. This could be used to make liquid CO_2, but to avoid the high costs of transporting cylinders of liquefied gas, new production methods were required. The first facility was established in Berlin in 1889 to make carbon dioxide from flue gases.

Since the turn of the century, a great many uses for carbon dioxide have been identified, and several other methods of manufacture have assumed commercial importance.

2. Physical Properties

Carbon dioxide [*124-38-9*], CO_2, M_r 44.010, is a colorless, odorless, nonflammable gas with a slightly sour taste. The regions of existence of the three phases are shown in Figure 1, the entropy – temperature diagram, and Figure 2, the enthalpy – pressure diagram [15]. Table 1 presents vapor pressure, density, and thermal data [16]. Detailed tables of physical, thermodynamic, and transport properties of solid, liquid, and gaseous carbon dioxide, together with a complete record and critical analysis of the original measurements, are available [17]. The physicochemical properties of carbon dioxide are summarized in references [18] and [19].

Gas density (0 °C, 0.1 MPa)	1.977 kg/m^3 (STP)
Specific density (compared with air)	1.5291
Molar heat c_p at 25 °C	37.13 J mol^{-1} K^{-1}
Entropy S_0	213 J mol^{-1} K^{-1}
Heat of formation ΔH	−393.51 kJ/mol
Free energy of formation ΔG_0	−394.2 kJ/mol
Specific heat c_p (gas, 0.1 MPa)	
at 0 °C	0.8277 J g^{-1} K^{-1}
at 20 °C	0.8459 J g^{-1} K^{-1}

Figure 1. Phase diagram of carbon dioxide, 0 – 1200 MPa and −100 to +200 °C

Of all liquids, water is almost the least effective medium for dissolving CO_2. The solubility in many other liquids is much higher. Table 2 shows a few examples.

Solubility of CO_2 in water: Henry's law is approximately valid up to CO_2 partial pressures of about 500 kPa. At low temperature and high pressure there is a severe deviation (see Table 3 [23], [24]).

Figure 2. Enthalpy – pressure – temperature – entropy diagram for carbon dioxide (entropy, S, has the units $\mathrm{J\,g^{-1}\,K^{-1}}$)

Heat of solution of gaseous CO_2 in water:

at 18 °C	19.92 kJ/mol
at 25 °C	20.30 kJ/mol

The solubility in ice at −5 °C to −20 °C is much less than in water at 0 °C [25].

The relationship between the dew point and the water content of CO_2 is shown in Figure 3.

Figure 3. Dew point curve for carbon dioxide

The solubility of CO_2 in salt solutions and acids is given in ref. [20, p. 1210].

3. Chemical Properties

At normal temperature, gaseous carbon dioxide is not very reactive. The carbon dioxide molecule is relatively stable and does not readily break down into simpler compounds. Some decomposition may be effected, however, by the use of high temperature, ultraviolet light, or electrical discharge.

$$CO_2 \rightleftharpoons CO + 0.5\,O_2$$

Reactions between carbon dioxide and other substances are generally effected only at high temperature or by use of catalysts. Reduction to carbon monoxide [*630-08-0*] occurs by the reaction with hydrogen, the reverse of the water-gas shift reaction.

$$CO_2 + H_2 \rightleftharpoons CO + H_2O$$

Carbon monoxide is also formed by reaction with carbon [*7440-44-0*] at elevated temperatures.

$$CO_2 + C \rightleftharpoons 2\,CO$$

The latter reaction is of considerable importance in the smelting of iron ore; coke and limestone are also added to the furnace. The limestone first decomposes to form carbon dioxide, which is then reduced to carbon monoxide by the hot coke. Reduction of the iron ore to the metal is then effected by the carbon monoxide.

Carbon dioxide may be reduced to carbon by the action of metals (e.g., aluminum [*7429-90-5*] or magnesium [*7439-95-4*]) at high temperature; the reduction can be controlled so that it goes only part way (e.g., by using tin as the metal). Data for gas reactions in which carbon dioxide is either formed or decomposed are shown in Table 4 [26].

Several other reactions involving carbon dioxide are of commercial importance. Its reaction with ammonia [*7664-41-7*] forms ammonium carbamate [*1111-78-0*], which when dehydrated yields urea [*57-13-6*], a compound of considerable importance as a concentrated fertilizer and as a reagent in the plastics industry.

$$CO_2 + 2\,NH_3 \longrightarrow NH_2COONH_4$$

$$NH_2COONH_4 \longrightarrow NH_2CONH_2 + H_2O$$

2000	60.709	50.535	−258.954	309.488	10.3258	2.117×10^{10}	2.8633	7.299×10^{3}
3000	62.802	54.345	−280.976	335.321	6.8437	6.977×10^{6}	0.5065	3.210

The liberated water can combine with the carbamate to produce ammonium carbonate [*506-87-6*] or ammonium hydrogencarbonate [*1066-33-7*].

$$NH_2COONH_4 + H_2O \longrightarrow (NH_4)_2CO_3$$

$$(NH_4)_2CO_3 \longrightarrow NH_4HCO_3 + NH_3$$

A gaseous mixture of carbon dioxide, carbon monoxide, and hydrogen [*1333-74-0*] can be converted to methanol [*67-56-1*] at moderate temperature and pressure by means of a copper – zinc catalyst.

$$CO_2 + 3\,H_2 \underset{\text{cat.}}{\rightleftharpoons} CH_3OH + H_2O$$

Addition of carbon dioxide to sodium phenolate [*139-02-6*] yields the sodium salt of salicylic acid [*54-21-7*], which is important in the manufacture of aspirin.

The solid octahydrate of carbon dioxide, $CO_2 \cdot 8\,H_2O$ [*27592-78-5*], can be formed if the gas is kept in contact with water at low temperature and high pressure.

Carbon dioxide in water solution is somewhat more reactive. Carbon dioxide dissolves in water to form a weak acid, carbonic acid [*463-79-6*], which undergoes reactions typical of such an acid. The following equilibria are set up:

$$CO_2\,(aq) \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons 2\,H^+ + CO_3^{2-}$$

In a solution of carbon dioxide in water, only ca. 0.1 % exists in the form of carbonic acid. The apparent primary dissociation constant (4.31×10^{-7} mol/L at 25 °C) suggests that the carbon dioxide solution is only weakly acidic in nature. This figure is based on the assumption that all the carbon dioxide dissolved and undissociated is present as H_2CO_3, but this is wrong. If the dissociation constant were based on the actual amount of H_2CO_3 present, then the acid would be regarded as moderately strong. (The actual primary dissociation constant is about 4×10^{-4} mol/L at 25 °C.) The apparent secondary ionization constant is 5.61×10^{-11} mol/L at 25 °C. At atmospheric pressure the pH of a carbon dioxide solution is 3.7; at a pressure of 560 kPa it is 3.3 and remains at this level at still higher pressures.

The rate at which carbon dioxide comes into equilibrium with H_2CO_3 and its dissociation products is slow, but the neutralization of H_2CO_3 by hydroxyl ions occurs instantaneously:

at pH < 8	$CO_2 + H_2O$	$\rightleftharpoons H_2CO_3$	slow
	$H_2CO_3 + OH^-$	$\rightleftharpoons HCO_3^- + H_2O$	instantaneous
at pH > 10	$CO_2 + OH^-$	$\rightleftharpoons HCO_3^-$	slow
	$HCO_3^- + OH^-$	$\rightleftharpoons CO_3^{2-} + H_2O$	instantaneous

at pH 8 – 10 both mechanisms operate.

As a dibasic acid, carbonic acid can react to form hydrogencarbonates ($M^{I}HCO_3$) and carbonates ($M^{II}CO_3$). All hydrogencarbonates are

readily soluble in water and yield carbon dioxide when heated; these properties are important in the industrial recovery of carbon dioxide. All carbonates are relatively insoluble in water except those of the alkali metals.

4. Occurrence in Nature

Carbon dioxide occurs naturally in the earth's lithosphere, hydrosphere, and atmosphere. A balance exists between the processes by which it is produced and used up.

4.1. Lithosphere

The lithosphere is that part of the earth not covered by the oceans. An estimated 5.5×10^{16} t of carbon dioxide is bound in the earth's crust in the form of carbonates of calcium (chalk), magnesium (dolomite), and other metals and as a constituent of many organic compounds. All igneous rocks, when heated strongly under vacuum, emit a mixture of gases, the principal constituents of which are usually carbon dioxide, water, and hydrogen. Rocks containing carbonate easily yield carbon dioxide when heated as do bituminous shale materials. Gases constantly escape from the surface of the earth at volcanoes and eruptive vents as a result of the action of heat on the rocks of the earth's crust. Carbon dioxide is a constituent of nearly all of these gaseous mixtures, in concentrations ranging from a few percent to nearly pure CO_2. Many of these sources have long been known to have adverse effects on living organisms.

In addition to that given off as a gas, much carbon dioxide escapes from the earth in natural spring water. Two main classes of such water are known: those which are saturated with carbon dioxide under a partial pressure (as in normal air) and those containing carbon dioxide dissolved under pressure such that, as they come to the surface, the pressure is released and they effervesce. Carbon dioxide has been dissolved in these waters by a process occurring inside the earth. Because of the presence of the carbon dioxide, these waters are acidic and thus more likely to dissolve rock, hence the name "mineral waters".

4.2. Atmosphere

The atmosphere includes all of the gases surrounding the earth. Carbon dioxide is present in the earth's atmosphere at a level of about 0.03 % by volume. The exact level is dependent on the exact position on the earth's surface at which the sample is taken, the quantity of vegetation present, and the time of day (the level being higher at night). The total amount of carbon dioxide in the atmosphere is about 2.3×10^{12} t.

Processes which expel carbon dioxide into the atmosphere are numerous. In addition to the evolution of the gas from the earth via springs, wells, and volcanoes, various other mechanisms produce carbon dioxide. Combustion of carbonaceous material, respiration of plants and animals, decay of organic material, and industrial processes such as lime-burning and the production of hydrogen and ammonia all generate gaseous carbon dioxide.

There are also various processes that remove carbon dioxide from the air, e.g., photosynthesis, weathering of rocks, and chemosynthesis by certain bacteria. The interrelationship of these generating and consuming processes is described in Section 4.4.

4.3. Hydrosphere

The hydrosphere comprises the oceans, seas, lakes, streams, and other bodies of water upon the earth. The concentration of carbon dioxide in the seas and oceans varies widely, but an average figure may be taken as five volumes of gas per ten thousand volumes of water. The total CO_2 content of the seas and oceans is about 1.4×10^{14} t.

In sea water, carbon dioxide exists as carbonates, hydrogencarbonates, carbonic acid, and as the dissolved gas itself. The amount of carbonate is usually fixed, but the hydrogencarbonate is labile and will give up gaseous carbon dioxide if the temperature of the water increases or the partial pressure of carbon dioxide above it diminishes. A dynamic equilibrium thus exists whereby the colder parts of the ocean absorb CO_2 and the warmer parts expel it to the atmosphere.

4.4. Biosphere

4.4.1. Life Cycle

The biosphere comprises all living things. Carbon dioxide is an essential substance in the life cycle of plants and animals and, as such, is basic to all life on earth. It is absorbed from the atmosphere by the leaves of plants. By using energy from sunlight and the accelerating influence of chlorophyll [*1406-65-1*], it reacts with water to form glucose [*50-99-7*].

$$6\,CO_2 + 6\,H_2O \xrightarrow[\text{chlorophyll}]{h\nu} C_6H_{12}O_6 + 6\,O_2 \qquad \Delta H = 2803\ \text{kJ/mol}$$

Glucose is subsequently converted by the plant into sugar and starch. All animals depend ultimately on vegetable matter for their food, and convert these carbon compounds built up by plants into carbon dioxide and water. Energy is simultaneously released. This reaction is the reverse of photosynthesis.

$$C_6H_{12}O_6 + 6\,O_2 \longrightarrow 6\,CO_2 + 6\,H_2O \quad \Delta H = -2803\ \text{kJ/mol}$$

Thus, carbon is being continually exchanged between the bodies of plants and animals. Atmospheric carbon dioxide is the medium of this exchange.

4.4.2. Radiocarbon Dating

An interesting and useful application of atmospheric carbon dioxide is the determination of the age of organic matter. Naturally occurring carbon contains 98.89 % ^{12}C, 1.11 % ^{13}C, and traces of ^{14}C. Cosmic rays interact with nitrogen in the upper atmosphere to form ^{14}C. This then decays with a half-life of 5570 years, sufficient time for it to become thoroughly mixed into all living organisms, which are in equilibrium with atmospheric carbon dioxide. When such organisms die, the ^{14}C contained within them decays and is not replenished. By comparing this quantity with the proportion of radioactive carbon existing in present-day organisms, the age of the specimen can be determined with an accuracy of ± 5 %.

5. Environmental Effects

Other processes serve to increase significantly the level of carbon dioxide in the atmosphere, in particular the combustion of fossil fuels. Since the advent of the industrial revolution, the burning of oil, natural gas, and coal has increased dramatically, and measurements of atmospheric carbon dioxide levels over the last 25 years have shown that there is an annual increase on the order of 1 mg/kg [27]. Although it is generally acknowledged that atmospheric carbon dioxide levels are increasing, scientists disagree as to the likely effects of such an increase [28]. One theory is based on the ability of carbon dioxide to absorb and transmit radiation. Carbon dioxide is transparent to the sun's incoming shortwave radiation, but it absorbs the longwave radiation emanating from the earth's surface. An increase in the atmospheric carbon dioxide level could cause an increase in the earth's temperature by this mechanism, known as the "greenhouse effect" (the glass in a greenhouse performs the same function as the carbon dioxide). The ultimate effects of this temperature rise might be radical changes in climate and rainfall patterns and a rapid rise in the sea level caused by the melting of polar ice. Other scientists argue that there may be other contributing factors in the regulation of the earth's temperature and that the carbon dioxide question should not be addressed in isolation.

6. Production

Much of the carbon dioxide generated in the world is a byproduct of ammonia and hydrogen production which make much more carbon dioxide than is ever recovered. Other sources are still exploited, but these are generally less efficient, and financially less attractive.

6.1. Carbon Dioxide from Ammonia and Hydrogen Plants (Process Gas CO_2)

The process for the production of ammonia is outlined in Figure 4. Desulfurization of the hydrocarbon feedstock (e.g., natural gas, naphtha) is carried out before catalytic steam reforming of the hydrocarbon to give a gaseous mixture of

Figure 4. Schematic representation of an ammonia plant

hydrogen, carbon dioxide, and carbon monoxide. Air is added and further steam reforming is effected in a gaseous mixture that then also contains nitrogen [*7727–37–9*]. Because only hydrogen and nitrogen are required to make ammonia, the carbon oxides are removed from the gas stream. Most of the carbon monoxide is catalytically converted to carbon dioxide, and the latter is removed by dissolution under pressure.

In the manufacture of hydrogen, the process is very similar, with the obvious omission of the addition of the air. Thus, in both cases, carbon dioxide must be removed before the process-gas stream can be used. Several methods are available; all are based on the absorption of carbon dioxide into a solution, under pressure, which flows countercurrent to the process-gas stream. The absorbed gas is liberated in a separate vessel by raising the temperature and lowering the pressure above the solution. Under the normal process conditions, the solubility of carbon dioxide in water is too low for this to be used as the absorbent. The solubility is enhanced by adding a solute to the water so that chemical combination of carbon dioxide with the solution is effected.

Figure 5. Carbon dioxide removal systema) Absorber; b) Regenerator

Alkali metal carbonates and ethanolamines have been employed in this capacity [29], [30].

6.1.1. Potassium Carbonate Process

The potassium carbonate [*584–08-7*] process is based on a reversible reaction.

$$K_2CO_3 + H_2O + CO_2 \rightleftharpoons 2\,KHCO_3$$

The rate of carbon dioxide absorption increases with decreasing temperature, increasing partial pressure of the gas, and increasing concentration of potassium carbonate solution. Figure 5 shows the usual arrangement of absorber and regenerator. The absorption should take place at a lower temperature than that of regeneration to maximize the amount of gas removed and recovered. This is achieved by a two-stage absorption and regeneration system. The solution containing carbon dioxide is pumped from the base of the absorber to the top of the regeneration column, supplied with a reboiler at its base. The solution is returned to the absorber from two points on the regenerator. Part of the solution is withdrawn from an intermediate point and is only partially regenerated; this is pumped to an intermediate point on the absorber. The remainder is withdrawn from the base of the regenerator. It is more completely regenerated, and is pumped, after it is cooled, to the top of the absorber. The carbon dioxide and water vapor mixture released in the regenerator is cooled. The water condenses out and the carbon dioxide is passed to the liquefaction plant.

Most commercial potassium carbonate systems also employ a catalyst to accelerate the rates of absorption and desorption of carbon dioxide. Corrosion inhibitors are also added to

the solution. Three processes are in most common use: the Benfield process (using diethanolamine [*111-42-2*] as catalyst and vanadium pentoxide [*1314-62-1*] as corrosion inhibitor), the Vetrocoke process (using arsenic trioxide [*1327-53-3*] as catalyst), and the Catacarb process (using unspecified additives).

6.1.2. Ethanolamine Process

The ethanolamine process, developed by the Girdler Corporation, uses an aqueous solution of ethanolamine instead of potassium carbonate. Monoethanolamine [*141-43-5*] reacts with carbon dioxide and water to form monoethanolamine carbonate [*21829-52-7*].

$$2\,HOC_2H_4NH_2 + H_2O + CO_2 \rightleftharpoons (HOC_2H_4NH_3)_2CO_3$$

6.2. Carbon Dioxide from Flue Gases

Carbon dioxide is a component of all flue gases produced by the complete combustion of carbonaceous fuels. Typical concentrations of carbon dioxide in such gases are 10 – 18 vol %. A schematic diagram of the process for recovering the carbon dioxide fraction of the gases is shown in Figure 6.

Figure 6. Carbon dioxide production from flue gases

The flue gases, after being cooled and cleaned by passing through a water scrubber, are passed through an alkaline carbonate solution or an amine solution which absorbs carbon dioxide. Unlike carbon dioxide from an ammonia plant, the product obtained from flue gases is generally contaminated with small amounts of sulfur compounds.

Although manufacture of carbon dioxide by this method was once of a considerable commercial importance, it is now seldom economically viable. It is, however, being revived in the United States for enhanced oil recovery projects, which require vast quantities of CO_2 [30], [32]. A refined process for recovering CO_2 from flue gases has been developed jointly by Dow and Procon [33]. It involves first mixing the flue gas with natural gas in an enrichment boiler. This mixture burns and thus removes the oxygen contained in the flue gas. In this way additional CO_2 is produced. The gas from the flue of the boiler is then fed to an absorption – regeneration system. The CO_2 is removed by using a concentrated aqueous solution of an amine, which also contains corrosion inhibitors, and is liberated by using steam supplied from the enrichment boiler [34].

A further development in the removal of carbon dioxide from flue gases, announced by Dow, involves a two-stage process. Caustic soda [*1310-73-2*] or soda ash [*497-19-8*] is first used to remove sulfur dioxide [*7446-09-5*], before the gas stream is passed through an amine solution which removes the carbon dioxide. An unspecified solvent is used, which, it is claimed, enables the attainment of two to three times the carbon dioxide loading achievable with conventional systems [35].

6.3. Carbon Dioxide from Fermentation

Large quantities of carbon dioxide are generated by fermentation processes, and up to 80 % of this gas may be recoverable. Before being suitable for further use, however, the carbon dioxide must be freed of the impurities inherent in this method of manufacture, i.e., hydrogen sulfide [*7783-06-4*], sulfur dioxide, and various organic compounds such as aldehydes, acids, and higher alcohols and diols. Two general methods

are available to purify fermentation carbon dioxide. Both use water scrubbers to remove the bulk of the entrained material. The impurities are then taken out by passing through either an activated charcoal bed or solutions of potassium permanganate [*7722-64-7*] and potassium dichromate [*7778-50-9*]. The first method relies on adsorption, whereas the second involves chemical reactions. In the second case the gas must be treated further downstream to remove oxidation products formed in the earlier stages as well as any traces of the reagents used in the purification.

6.4. Carbon Dioxide from Carbonates

The production of carbon dioxide by the calcination of calcium carbonate [*471-34-1*] and magnesium carbonate [*546-93-0*] is no longer economically important.

6.5. Carbon Dioxide from Natural Sources

Natural sources of gases containing very high concentrations of carbon dioxide are present in various parts of the world. Often the gas is so pure that it only requires drying before liquefaction. The main impurities present in this source of carbon dioxide are methane [*74-82-8*] and hydrogen sulfide. These sources are becoming more important in areas where enhanced oil recovery is being practiced [32], [34], [36].

7. Purification of Carbon Dioxide before Liquefaction

Unlike carbon dioxide derived from fermentation processes, which requires considerable purification as described, most of the gas from other sources is very pure. It contains only trace amounts of foreign materials, usually sulfur compounds. Because the ultimate use of the gas often involves foodstuffs, these trace impurities must be removed since they often impart distinctive tastes and odors. This is achieved by the use of activated carbon. Drying of the gas is also very important, because insufficiently dried material tends, on liquefaction, to choke the lines in the plant. Activated alumina, silica gel, or molecular sieve beds are used for drying. Most plants are multistreamed and are equipped with beds that can be reactivated by means of hot carbon dioxide, nitrogen, air, or steam.

The level of foreign gases present in the carbon dioxide stream must be minimized to reduce the energy required to liquefy and concentrate the circulating gas. The solubility of gases in liquid carbon dioxide decreases with decreasing temperature. If any are present, they separate out easily during the liquefaction stage.

8. Liquefaction of Carbon Dioxide

The critical parameters of carbon dioxide, $T_{crit} = 31\,°C$, $p_{crit} = 7.4\,MPa$, show that the gas may be liquefied at any temperature between 31 °C and its triple point (−56.6 °C) by compression to the required liquefaction pressure at that particular temperature and removal of the heat of condensation. It is, therefore, possible to liquefy CO_2 near the critical temperature by using a pressure of 7.4 MPa and water as the coolant, but because it is often difficult to guarantee a constant water supply at temperatures below 20 °C, this method is less favored than one in which a refrigerant is used. In this second method, the gas is compressed under 2 – 4 MPa before being cooled to subzero temperatures by means of a refrigerant. The choice of refrigerant obviously is a function of the cost and availability of the likely materials at their point of use. The proximity of many carbon dioxide liquefaction plants to ammonia production facilities means that ammonia is often the preferred refrigeration medium. Fluorocarbons and brine are used in some plants. A typical carbon dioxide liquefaction plant is shown in Figure 7.

Raw carbon dioxide piped from the ammonia plant is cooled by water and then passed to the suction side of three parallel, three-stage, electrically driven reciprocating compressors. After compression under oil-free conditions, the gas is scrubbed with water to remove traces of organic material formed in catalytic stages of the purification train of the ammonia process. Two further purification stages are then carried out, and traces of oil and sulfur compounds are removed in an activated charcoal bed. The gas then passes through one of a pair of parallel driers containing

Figure 7. Schematic representation of a CO_2 liquefaction plant

activated alumina. The water content is reduced to mg/kg levels. (The alumina absorbent is periodically regenerated by passing a countercurrent of warm, dry carbon dioxide through the bed.) The dried, purified carbon dioxide is then liquefied in a double-pass condenser, using liquid ammonia at $-12\,^{\circ}C$ as refrigerant. The gaseous ammonia resulting from the transfer of heat is passed back to the plant ammonia-gas main. The liquefied carbon dioxide is passed down a stripping column in which entrained permanent gases (hydrogen, nitrogen, and methane) are removed by a countercurrent flow of purer carbon dioxide gas from recycle compressors. This stripping gas is the flash gas from the storage vessels of liquid carbon dioxide. The carbon dioxide from the top of the column, now rich in permanent gases, joins the main gas stream from the compressors and goes on to the condenser. Purging of the permanent gases is effected by means of a pressure-controlled blow-off to the atmosphere.

The pressure is lowered and the liquid carbon dioxide is sent to storage tanks, from which both road and rail tankers may be filled. The liquid may also be processed further to form dry ice.

9. Production of Dry Ice

Dry ice is thus named because it sublimes without residue. It is formed as a snow when liquid carbon dioxide is allowed to expand to atmospheric pressure. The density of this snow is 0.4 – 0.6 kg/L. Commercial manufacture of dry ice involves the densification of this loose snow by means of a hydraulic press to form solid blocks of material of density 1.5 – 1.6 kg/L. A typical unit for the production of dry ice is shown in Figure 8.

Liquid carbon dioxide is piped from the liquid storage facility, and the pressure is reduced in a suitable vessel. The resultant flash gas is passed back to the gas system. A measured dose of the liquid is then fed into one of several presses, where it is allowed to expand. Solid carbon dioxide forms along with some carbon dioxide gas. This flash gas is also returned to the gas system. When off-gassing is complete, the solid material is compressed and ejected as a large block, which is conveyed on a belt to an automated system of band saws. The block is cut into smaller pieces, the final size being $25 \times 19 \times 19$ cm. The dry ice is then weighed, wrapped, and packed into large, insulated containers. If smaller slices

Figure 8. Schematic representation of the ICI Drikold plant for the production of dry ice

are required (e.g., for use on aircraft), further automated slicing and wrapping is carried out.

It is important that the carbon dioxide used in this process is free from moisture, which can block the lines and cause the formation of crumbly dry ice.

Continuous loss of carbon dioxide by sublimation and consequent diminution in size of the blocks is inevitable during storage of dry ice. It is necessary, therefore, to schedule production carefully so that the product is made as near as possible to the time it is used.

Since considerable handling of solid carbon dioxide is involved in the manufacture of dry ice, automation of the plants is common, to minimize costs, maximize efficiency, and improve hygiene.

Solid carbon dioxide is also made in pellet form. Typical pellet dimensions are 1 cm in diameter and 1 – 3 cm in length. Pellets are advantageous to customers who would normally break up the larger blocks before use, but pellets have the disadvantage of being much more susceptible to sublimation because of their greater surface-to-volume ratio. They also have a lower bulk density (0.8 – 1.0 kg/L) and, thus, occupy more storage space.

10. Quality Specifications and Analysis

Most of the carbon dioxide produced is of a final purity greater than 99.7 % by volume, and purities of 99.9 % by volume should be achievable if sufficient care is taken with the purification stages. Carbon dioxide from ammonia and hydrogen plants is usually of a high degree of purity before being subjected to purification and liquefaction; therefore, use of this source of starting material facilitates the production of very pure final product. Refined carbon dioxide from natural sources often still contains a small quantity of methane.

The necessary degree of purity is dependent on the final use to which the carbon dioxide will be put. Because a large proportion is used in the food and drink industries, the major criteria for the quality of the carbon dioxide are that it should be free of odor and taste. Thus, all contaminants which could contribute to these two properties (e.g., sulfur compounds, oils, and hydrocarbons) should be removed, preferably to less than mg/kg levels. The main impurities present to any significant degree in the final purified product are usually nitrogen, oxygen [*7782-44-7*], and argon [*7440-59-7*] (from

air), and hydrogen and carbon monoxide (if the carbon dioxide came from a process-gas source).

To meet the quality specifications described above, the purified carbon dioxide is analyzed regularly, using both on-line techniques and laboratory analyses of samples taken from the plant. Permanent gases and hydrocarbons are usually monitored by chromatographic techniques, and sulfur compounds, oil, and other trace impurities are determined by using standard analytical procedures. The moisture content of the carbon dioxide is determined by hygrometry.

The use of carbon dioxide in the food and drink industries is subject to the foodstuffs regulations in effect in the particular country of use. In some cases, it is necessary to carry out microbiological tests.

11. Commercial Forms, Storage, and Distribution

Carbon dioxide is marketed as a liquid or solid, and since the early 1960s the sale of liquid CO_2 has exceeded that of the solid form.

11.1. Solid Carbon Dioxide

Solid CO_2, commonly called dry ice, is formed below the triple point of CO_2, and there are a variety of patented devices for its production. Generally, a conversion of about 60 % liquid to solid is achieved, the flash gas being recycled. The product snow is either compressed into blocks of 10 – 25 kg or extruded into pellets of various sizes. Because dry ice continually sublimes even in well-insulated containers, it is rarely stored at the point of manufacture, but is made and distributed on demand. Dry ice is distributed in insulated containers of varying capacity that should be designed to keep losses to less than 3 % per day. Individual blocks or packs are sold from supply depots.

11.2. Liquid Carbon Dioxide

Liquid CO_2 is generally stored in bulk at −18 °C and 2.1 MPa in insulated vessels fitted with refrigeration units, level gauges, and relief valves. The vessels are normally fabricated of stainless or low-carbon mild steel. If the latter is used, national design codes may impose the need for stress relief to guard against low-temperature embrittlement. The lowest in-service temperature possible is that of solid CO_2, −78 °C. The imposition of furnace stress relief could limit the capacity of a mild-steel vessel to about 250 t.

Liquid CO_2 is distributed in cylinders or in bulk. In cylinders, CO_2 is at ambient temperature and high pressure. Cylinders are filled by means of a compressor to a filling ratio dependent on the expected storage temperature, i.e., temperate climate ratio = 0.75, tropical climate ratio = 0.67.

$$\text{Filling ratio} = \frac{\text{weight of liquid } CO_2 \text{ permitted}}{\text{water capacity by weight of cylinder}}$$

Stringent national design codes cover the manufacture of cylinders, and there are also codes of practice for their storage and handling. All CO_2 cylinders should be fitted with bursting discs. Bulk liquid CO_2 is distributed by road or rail in insulated containers at the same temperature and pressure as in storage. Generally, these containers are not refrigerated, and they are usually designed to allow for a pressure rise of 50 – 100 kPa per day. They are fitted with relief valves. Road tankers are fitted with transfer pumps and are of a capacity limited only by the gross vehicle weight. Rail tankers are not normally fitted with transfer pumps and can have a payload of up to 200 t. The capacity of storage tanks of the customer can be 1 – 250 t. These vessels are usually insulated, refrigerated, and fitted with pressure gauges and relief valves. Transfer from road or rail tanker to customer is normally achieved by equalizing the pressure between the two vessels in the gas phase and then pumping. As a rule, the consumer requires CO_2 in the gas phase and can achieve this either by direct removal of the gas phase from his storage vessel or, should the quantity required exceed the conversion rate of liquid to gaseous CO_2 by the natural heat leak of the vessel, convert liquid to gas by means of a steam, hot water, or electrically heated vaporizer.

12. Uses

12.1. Uses of Gaseous Carbon Dioxide

A large proportion (ca. 50 %) of all the carbon dioxide recovered is used at the point of production to make further chemicals of commercial importance, mainly *urea* and *methanol.* In these applications the carbon dioxide is used in its gaseous form, and its chemical properties are of prime importance. A further important use of carbon dioxide close to the source of the gas is in *enhanced oil recovery* in the United States [32]. In this application, CO_2 is added to aging oil wells to increase production of oil. To bring crude oil to the surface, a driving force must be present. In new wells this is provided by gases dissolved in the oil. As the well ages, other sources of energy are needed. Water is often used, and finally, a miscible gas, such as carbon dioxide, is added to reduce the interfacial forces of the entrained oil droplets and, thus, mobilize the remaining reserves. The source of carbon dioxide for this application if often natural wells adjacent to the oil well. Extensive CO_2 gathering and distribution facilities are required for this application [37]. Subsequent separation and recycling of the used CO_2 from mixtures also containing hydrocarbons is often carried out [38]. In this application, membranes have been used as the first stage of a three-stage removal process, while the second and third stages use amine solutions. The membrane system consists of many hollow fibers, over which the gas mixture passes; CO_2 is preferentially adsorbed on the surface of the fiber and diffuses through the membrane material into the hollow center. Up to 60 % of the CO_2 present in the gas mixture can be removed by this first stage.

The remainder of the carbon dioxide generated worldwide is converted to either liquid or solid form for use elsewhere, or is vented to the atmosphere, since transportation of gaseous carbon dioxide is not economically viable.

12.2. Uses of Solid Carbon Dioxide

Dry ice was originally the more important of the two nongaseous forms of carbon dioxide. Its use first became popular in the United States in the mid-1920s as a refrigerant for the preservation of food, and in the 1930s it became an important factor in the growth of the ice cream industry. Solid carbon dioxide was favored over the liquid form, which could only be moved about in cylinders. Road tankers had not been developed at that time.

The refrigeration range of dry ice extends to −78 °C at atmospheric pressure (lower temperatures can be achieved at reduced pressures). The reasons for the emergence of solid carbon dioxide as a refrigerant were threefold: it leaves no residue on evaporation, is not heavy, and may be allowed to come into direct contact with food because it is nontoxic. After World War II, changes in compressor design and the availability of special low-temperature steels made it possible to liquefy carbon dioxide on a very large scale. Liquid carbon dioxide consequently began to replace dry ice in many applications. The uses for which dry ice is still favored are essentially small-scale applications, where weight is an important factor, e.g., in the transportation of refrigerated food by road and air.

12.3. Uses of Liquid Carbon Dioxide

The uses of liquid carbon dioxide are many, and range from those in which the chemical composition is important to those in which it is not. In some applications, the liquid carbon dioxide may be converted to the gaseous form immediately prior to use.

12.3.1. Use as an Inert Environment

In these applications, carbon dioxide is used instead of an air atmosphere because the presence of air would cause an undesirable effect.

In the handling and transportation of foodstuffs, oxidation leading to a loss of flavor, or the growth of bacteria can be prevented by using carbon dioxide. Beer and lager are canned and bottled under carbon dioxide, and these liquids may also be transported by using carbon dioxide under pressure. Coffee is packed under carbon dioxide, and fruit, vegetables, and cereals are transported in an atmosphere of the gas. In such cases, the nontoxic nature of carbon dioxide is obviously very important. It competes with nitrogen as an inert medium in this application,

and the choice of gas is dependent on the relative costs of the two gases at the particular location.

Carbon dioxide is particularly suitable for use in fire extinguishers because it is heavier than air and extremely stable. It may be used on fires for which water cannot be used effectively, e.g., electrical or oil fires. Because carbon dioxide evaporates without residue and is nontoxic, its use does not result in further damage or contamination to the materials being treated.

Carbon dioxide is used extensively as a shielding gas in arc welding [39], in which its function is to protect the welding zone from the deleterious effects of oxygen, nitrogen, and hydrogen. Only a few gases possess the required shielding properties, and the alternatives to carbon dioxide (rare gases, particularly argon) are more expensive. Carbon dioxide may be used either in place of the rare gas or in conjunction with it, depending on the material to be welded.

A further use of carbon dioxide as an inert medium is in the movement of liquids which are either flammable or susceptible to deterioration by oxidation.

12.3.2. Promoting the Growth of Plants

The importance of carbon dioxide in the growth of plants has already been outlined. This is exploited by fruit and vegetable growers (particularly in the United Kingdom and the Netherlands), who introduce the gas into their greenhouses to give levels greater than that normally present in air (e.g., 1000 mg/kg compared with 300 mg/kg). The plants respond by raising their assimilation rate of carbon dioxide, and an increase in yields of about 15 % is achievable [40].

12.3.3. Heat Transfer Medium in Nuclear Power Stations

Carbon dioxide is used in certain nuclear power reactors as the intermediate heat transfer medium. It transfers heat from the fission processes to steam or boiling water in heat exchangers. It thus serves as a reactor coolant while indirectly generating steam for electrical power. Carbon dioxide is favored in this application because it does not become significantly radioactive and is available in large quantities with a high degree of purity. It is also substantially cheaper than alternative gases such as helium [*7440-59-7*]. Some radiolysis to CO and O may occur, but catalytic recombination units are fitted into the gas stream to regenerate the CO_2.

12.3.4. Refrigerant

The advantages of carbon dioxide as a refrigerant in the food industry have been described in Section 12.2. Liquid carbon dioxide is used extensively to freeze food (particularly in the United States) and also for its subsequent storage and transport.

Molded rubber and plastic components may be trimmed (deflashed) by rapid freezing with liquid carbon dioxide and tumbling in a barrel. The flash, being frozen and brittle, may easily be removed by this process, leaving smoothly trimmed items. This method is cheaper and quicker than hand or machine trimming.

12.3.5. Uses Based on the Solubility of Carbon Dioxide

Carbon dioxide has a moderate solubility in water, and use is made of this property in the production of both nonalcoholic and alcoholic effervescent drinks. This was the first major application of carbon dioxide.

The use of carbon dioxide in the aerosol industry is increasing steadily. This application depends on its solubility in the product to be dispensed [41]. The nontoxic nature of carbon dioxide makes it particularly suitable for aerosols of foodstuffs (e.g., whipped cream).

12.3.6. Chemical Uses

In the carbon dioxide – silicate process for the production of foundry molds and cores, use is made of the chemical reaction between carbon dioxide and silica, which serves to bind together the sand grains [42]. The mold is ready for use immediately, and intricate molds can be made in a very short time.

Sodium salicylate, one of the intermediates in the manufacture of aspirin, is made by the reaction of carbon dioxide with sodium phenolate.

Carbonation of softened waters is carried out by using carbon dioxide to eliminate the precipitation of insoluble lime compounds.

Carbon dioxide also finds use in the production of basic lead carbonate [*598-63-0*] and sodium, potassium, and ammonium carbonates and hydrogen carbonates. It is used as a neutralizing agent in mercerizing operations in the textile industry because it is more convenient to use than sulfuric acid [*7664-93-9*].

12.3.7. Other Uses

Liquid carbon dioxide is used in a coal mining process, in which it is fed down the mine shaft and on subsequent rapid expansion shatters the coal. High-pressure extraction of natural products, using liquid carbon dioxide as a solvent, may be used to isolate particular flavorings and fragrances.

Carbon dioxide has a multitude of other uses that account for only a relatively small amount of the product's use. Anesthetizing of animals prior to slaughter, cryobranding of animals, generating fog for theatrical productions, freezing of benign tumors and warts, lasers, production of lube oil additives, tobacco processing, and preburial sanitization are examples of such uses.

13. Economic Aspects

Only about half of all the carbon dioxide generated is recovered. Of this, approximately half is used at the source for the production of urea and methanol, or in enhanced oil recovery. The remainder is sold in the liquid or solid form.

Estimates of the total amounts of liquid and solid carbon dioxide produced throughout the world are of the order of several millions of tons per year in the United States, approximately one million tons per year in Europe (Great Britain, Germany, and France each produce a few hundred thousand tons per year), and approximately half a million tons per year in Japan. The proportion of this total that is made up of solid carbon dioxide has declined steadily since the 1950s, because liquid carbon dioxide has taken over many of its applications. Dry ice is estimated in 1985 to account for 10 – 20 % of the total.

The cost of transporting carbon dioxide is very high compared with the cost of production; thus, the vast majority of the carbon dioxide recovered is used in the country where it is made.

The major supply of carbon dioxide is dependent on the operation of plants for the production of other primary products (e.g., ammonia), the demand for which obviously depends on other factors (e.g., the variable demand for fertilizer). The value of the carbon dioxide produced is thus intimately linked to these other factors. For example, in 1985, the United States produced and consumed about four million tons of carbon dioxide worth more than $ 260 000 000 [43].

14. Safety Precautions

Carbon dioxide is a colorless, odorless, noncombustible, and nontoxic gas. Because it is heavier than air, it spreads along the ground. Although it forms a portion of exhaled air, high concentrations of carbon dioxide in respirable air can lead, without significant observable signs, to asphyxia. The TLV-TWA is 0.5 % by volume and the TLV-STEL is 1.5 % by volume [44]. This figure may be raised to 3.0 % by volume if the notice of intended changes (for 1984 – 85) proposed by the ACGIH is adopted. At 5 % by volume, there is an approximately threefold increase in breathing rate, and concentrations above this level rapidly lead to unconsciousnes and death. It is necessary, therefore, to ensure that adequate ventilation is provided in establishments where carbon dioxide is handled to prevent the accumulation of the gas in the respirable air.

Carbon dioxide monitoring equipment is usually provided in areas where there is a likelihood of building up significant concentrations of the gas. Alarms sound if the concentration of carbon dioxide exceeds 0.5 %.

When solid carbon dioxide is handled, there is a risk of unpleasant skin burns, which are a severe form of frostbite. Thick gloves should be worn to prevent contact of the refrigerant with the skin. Medical attention should be sought for such burns.

1. Introduction

Carbon disulfide [*75-15-0*], CS_2, is an important industrial chemical with an extensive and well-developed chemistry. LAMPADIUS discovered carbon disulfide in 1796 while heating a mixture of iron pyrite and carbon. Industrial interest in this compound dates back to 1839, when it was prepared by SCHRÖTTER using charcoal and sulfur in a heated retort [1]. Its solvent power was recognized early, and for some time carbon disulfide was widely used for the extraction of fats and oils. It was, however, not until introduction in the early 1900s of the viscose rayon process, which uses carbon disulfide to solubilize cellulose, that it began to assume the role of a large-scale industrial chemical. By the late 1960s, competition from petroleum-based synthetic fibers began to affect the earlier rapid growth of rayon; the 1970s witnessed a decline of the rayon market and correspondingly that of carbon disulfide. Usage of carbon disulfide has since stabilized, and a small market growth is projected for the future.

Of the 1.1×10^6 t of carbon disulfide produced worldwide in 1984, over 75 % was used by the regenerated cellulose industry. The rest was consumed in production of carbon tetrachloride and miscellaneous organosulfur compounds used as rubber chemicals, flotation agents, and pesticides.

2. Physical Properties

Carbon disulfide is a volatile, dense liquid with a wide flammability range in air (1 – 50 vol %) [2]. It has an unusually low autoignition point (100 °C) and a low flash point (– 30 °C). Its evaporation rate into air is 1.6 times that of diethyl ether [3]. It is an excellent solvent for many organic compounds and readily dissolves sulfur, phosphorus, iodine, waxes, rubber, and resins. The commercial product has a pungent odor characteristic of sulfur compounds.

Some of the most useful physical, thermochemical, and transport properties of carbon disulfide are as follows (also see Table 1) [1], [4–13]:

M_r	76.13

3. Chemical Properties

The chemistry of carbon disulfide is extensive and well-investigated [1], [5], [14–16]. Comprehensive surveys of the inorganic chemistry of carbon disulfide have appeared [1], [5]. A detailed review of the organic reactions of carbon disulfide is given in reference [15].

Carbon disulfide reacts with sulfides, alcohols, ammonia and amines, and chlorine to give industrially important derivatives and intermediates. Aqueous alkalies react slowly with carbon disulfide to give the trithiocarbonate and carbonate:

$$3\,CS_2 + 6\,NaOH \longrightarrow 2\,Na_2CS_3 + Na_2CO_3 + 3\,H_2O$$

Trithiocarbonates are also formed with metal sulfides:

$$K_2S\ (\text{aqueous}) + CS_2 \longrightarrow K_2CS_3$$

Carbon disulfide reacts with alcoholic alkalies to produce xanthates (salts of dithiocarbonates) [17]:

$$ROH + NaOH \longrightarrow RONa + H_2O$$

$$RONa + CS_2 \longrightarrow ROCSSNa$$

This reaction is the basis for the viscose process in which cellulose is converted to the xanthate and regenerated as fibers and films:

$$(\text{cellulose})ONa + CS_2 \longrightarrow (\text{cellulose})OCSSNa$$

$$2\,(\text{cellulose})OCSSNa + H_2SO_4 \longrightarrow 2\,(\text{cellulose})OH + 2\,CS_2 + Na_2SO_4$$

Carbon disulfide reacts with ammonia and, depending on ammonia concentration and on temperature, forms ammonium dithiocarbamate (**1**) [*513-74-6*], ammonium trithiocarbonate (**2**) [*13453-08-2*], and ammonium thiocyanate (**3**) [*1762-95-4*] [14]:

$$CS_2 + 2\,NH_3 \longrightarrow \underset{\mathbf{1}}{NH_2CSSNH_4}$$

$$CS_2 + 6\,NH_3 + 3\,H_2O \longrightarrow \underset{\mathbf{2}}{2\,(NH_4)_2CS_3 + (NH_4)_2CO_3}$$

$$2\,CS_2 + 4\,NH_3 \longrightarrow \underset{\mathbf{3}}{(NH_4)_2CS_3 + NH_4(SCN)}$$

In the vapor phase and at higher temperature (150 – 160 °C), thiourea [*62-56-6*] is obtained via decomposition of the thiocyanate [14]:

$$NH_4(SCN) \longrightarrow SC(NH_2)_2$$

Reactions with primary and secondary amines produce principally the dithiocarbamate salts [18]:

$$2\,RNH_2 + CS_2 \longrightarrow RNHCSSNH_3R$$

$$2\,R_2NH + CS_2 \longrightarrow R_2NCSSNH_2R_2$$

In the presence of alkalies, many commercially important salts of dithiocarbamic acid are obtained:

$$R_2NH + CS_2 + NaOH \longrightarrow R_2NCSSNa + H_2O$$

Sodium methyldithiocarbamate [*137-42-8*], $CH_3NHCSSNa$, an important soil fumigant, is produced by the reaction of carbon disulfide with methylamine and an aqueous solution of caustic soda. In a similar reaction with ethylenediamine, the fungicide sodium ethylene bis(dithiocarbamate) [*142-59-6*] is the reaction product:

$$NH_2CH_2CH_2NH_2 + 2\,CS_2 + 2\,NaOH \longrightarrow \begin{array}{l} CH_2NHCSSNa \\ | \\ CH_2NHCSSNa \end{array} + 2\,H_2O$$

Two important vulcanization accelerators are products in the reaction of aniline with carbon disulfide. In the absence of sulfur, thiocarbanilide [*102-08-9*] is obtained:

$$C_6H_5NH_2 + CS_2 \longrightarrow C_6H_5NH\overset{\overset{\displaystyle S}{\|}}{C}NHC_6H_5 + H_2S$$

With sulfur, 2-mercaptobenzothiazole [*149-30-4*] (MBT) is produced:

$$C_6H_5NH_2 + CS_2 + S \longrightarrow$$  $$+ H_2S$$

Thiurium disulfides, a family of compounds used as fungicides and vulcanization accelerators, are formed by oxidizing dithiocarbamates [18]:

$$2\,R_2NCSSNa + H_2O_2 + H_2SO_4 \longrightarrow (R_2NCSS\text{-})_2 + Na_2SO_4 + 2\,H_2O$$

Chlorination of carbon disulfide gives rise to a host of chlorinated products [19]. At temperatures between 5 and 30 °C and in the absence of iron, iodine-catalyzed chlorination of carbon disulfide gives good yields of trichloromethanesulfenyl chloride [*594-42-3*]:

$$2\,CS_2 + 5\,Cl_2 \longrightarrow 2\,Cl_3CSCl + S_2Cl_2$$

Depending on the degree of chlorination, some carbon tetrachloride [*56-23-5*], sulfur dichloride [*10545-99-0*], and thiophosgene [*463-71-8*] are also formed.

In the presence of iron and metal chlorides and at higher temperature (70 – 100 °C), carbon tetrachloride and sulfur chlorides are exclusively obtained [14]:

$$CS_2 + 3\,Cl_2 \longrightarrow CCl_4 + S_2Cl_2$$

Further reaction of the sulfur monochloride [*10025-67-9*] with carbon disulfide produces more carbon tetrachloride and sulfur:

$$CS_2 + 2\,S_2Cl_2 \rightleftharpoons CCl_4 + 4\,S$$

These two reactions are the basis for the commercial production of carbon tetrachloride from the chlorination of carbon disulfide [20]. The reaction with chlorine is very fast and proceeds to completion. Carbon disulfide and sulfur (I) chloride react more slowly. The stoichiometric reaction is equilibrium limited at about 70 % at 90 °C.

Carbon disulfide reacts readily with water in the presence of alumina and oxide catalysts above 150 °C to form carbon dioxide and hydrogen sulfide:

$$CS_2 + 2\,H_2O \longrightarrow CO_2 + 2\,H_2S$$

Carbonyl sulfide is an intermediate in this hydrolysis reaction:

$$CS_2 + H_2O \longrightarrow COS + H_2S$$

$$COS + H_2O \longrightarrow CO_2 + H_2S$$

At 200 – 300 °C, equilibrium conversion of carbon disulfide is nearly complete [21].

At temperatures above 150 – 200 °C and in the presence of metal sulfide catalysts, notably molybdenum and nickel sulfides, carbon disulfide is reduced by hydrogen to give various amounts of methanethiol, dimethyl sulfide, methane, and hydrogen sulfide [22].

4. Production

Carbon disulfide is commercially manufactured by the reaction of sulfur with charcoal or methane. Ethane, propane, and propene have been used to a limited extent. Since the methane process was first introduced in the early 1950s, it has steadily supplanted the older charcoal process, which is no longer a factor in carbon disulfide manufacture in the United States, Europe, and Japan. In areas where natural gas or methane is not readily available or when plant size is relatively small, the charcoal process still supplies local viscose rayon requirements.

4.1. Thermodynamics and Rates of Reaction

The reactions of sulfur with either carbon or methane have been evaluated for the following equations [23]:

$$C_{(s)} + 2\,S_{(g)} \longrightarrow CS_{2\,(g)}$$

$$CH_{4\,(g)} + 4\,S_{(g)} \longrightarrow CS_{2\,(g)} + 2\,H_2S_{(g)}$$

The maximum yield from carbon was found to be 91 % at 720 °C. For the methane reaction, complete conversion was attained at 300 °C. In practice, higher temperature is required to provide economic reaction rates. The reactions are endothermic over most of the temperature range practiced commercially; the energy supplied is taken up mainly by vaporization and superheating of sulfur [23–25].

The thermodynamics of sulfur dissociation [7], [23], [24] determine the concentration of the reactive diatomic sulfur molecule, S_2; high temperature and low pressure favor high S_2 concentrations [7]. Equilibration rates of the vapor species, S_n ($n = 1-8$), are relatively fast so that equilibrium values of S_2 may be used in rate equation formulation.

Homogeneous and heterogeneous rate data for the reaction of methane and sulfur have been obtained for temperatures between 500 and 700 °C [26], [27–30]. The rate equation that best fits these data is one that is first order with respect to methane and S_2:

$$\text{rate} = k\,c_{CH_4}\,c_{S_2}$$

where k is the reaction rate constant. The following are the Arrhenius equations for the rate constants, based on reference [26]. For the homogeneous reaction:

$$k = 1.9 \times 10^6 \exp(-52000/RT)\ \text{mol}\,\text{h}^{-1}\,\text{cm}^{-3}\,\text{kPa}^{-2}$$

For the silica gel catalyzed reaction:

$$k = 7.7 \times 10^2 \exp(-28000/RT)\ \text{mol}\,\text{h}^{-1}\,\text{g}^{-1}\,\text{catal.}\,\text{kPa}^{-2}$$

Other values for these rate constants as well as space velocities for the catalyzed reaction have been reported [27–31]. At 600 °C, the homogeneous rate is about 1 % that for the silica gel catalyzed reaction.

4.2. Production from Charcoal and Sulfur

The basic process for the reaction of charcoal with sulfur has changed little since its inception in the mid 1840s. Externally heated retorts are still being used, although equipment design has undergone much improvement as better materials of construction have become available. Details on retort design are available in references [32], [33].

In retort plants [34], [35], molten sulfur is vaporized and superheated either before or after addition to the retort. Reaction between the superheated sulfur vapor and a stationary bed of charcoal at 850 – 900 °C takes place inside the retort at slightly above atmospheric pressure. The product gas, consisting of carbon disulfide, some sulfur, hydrogen sulfide, carbonyl sulfide, and inerts, passes through a train of condenser, scrubber, and oil absorber where the crude carbon disulfide is recovered; the pure product is obtained by further treatment in distillation columns. The tail gas, made up primarily of hydrogen sulfide, carbonyl sulfide, and inerts, is either incinerated and scrubbed with a caustic solution or routed to a sulfur recovery plant.

Typically, each retort can produce 1 – 3 t/d of carbon disulfide. High-temperature corrosion of the cast iron retorts limits their useful life to less than 1 year. The raw materials used in the retorts should be low in ash and residue to minimize the frequency of reactor cleanouts. Fouling of the retorts also restricts heat transfer and shortens retort life. Charcoal quality is extremely important because less reactive material requires higher temperature for satisfactory operation; charcoal derived from hardwood is preferred for this reason. The charcoal is normally precalcined at 500 °C to remove volatiles that could result in formation of objectionable byproducts. Thermal efficiency of retorts is ca. 25 %; carbon and sulfur yields are generally below 90 % [34–36].

Electrical resistance heating in brick-lined electrothermal reactors provides an alternative heat source for the reaction of charcoal with sulfur [37]. Where cheap power is available, the electrical method may be more economic. Power consumption as a function of carbon disulfide produced is ca. 1200 kW h/t. Other advantages

offered by electrothermal reactors are a larger capacity per reactor (up to 10 t/d) and a longer reactor life; furthermore, a wider range of solid carbon feed can be used because electrothermal reactors can generate higher temperatures.

4.3. Production from Methane and Sulfur

As demand for carbon disulfide rapidly increased in the 1940s, limitations of the charcoal processes provided the incentive for development of a more efficient large-scale method for its manufacture. Readily available cheap natural gas and favorable thermodynamics [21], [23], [31] led to the successful development of the process based on the catalyzed reaction of methane and sulfur [21], [27–31], [38], [39]. During the period 1943 – 1965, many patents were issued that covered various aspects of the process [38–54].

The commercial methane process [35], [55], [56] is based primarily on work described by the patents issued to the Pure Oil Co. [41–45]. The rights to these patents were acquired by the Food Machinery Corp. and Stauffer Chemical Co., and in 1953, the first methane process plant was built by FMC in South Charleston, West Virginia. This was followed by a Stauffer plant at LeMoyne, Alabama, three years later. By the mid 1960s all carbon disulfide in the United States was manufactured by this method; many similar plants soon followed in Europe and elsewhere [35]. Over 85 % of the world's production capacity is based on methane.

Figure 1 shows a typical methane process flow sheet. Purified natural gas containing over 95 % methane and low concentrations of propane and heavier hydrocarbons is preheated to about 250 °C in the convection section of the reaction furnace. The furnace is a typical box-type pyrolysis furnace commonly used in the petrochemical industry, with radiant and convection sections [57]. The hot methane gas is mixed with liquid sulfur and introduced into the horizontal heating coil located in the radiant section. There the liquid sulfur is vaporized, and the temperature of the mixture is raised to 550 – 650 °C. Operating pressure is typically 400 – 700 kPa. Alternatively, the methane and sulfur may be introduced separately and at different locations of the coil. A slight excess of sulfur (5 %) is used to ensure good methane conversion and to minimize carbon and tar formation.

To withstand the high-temperature corrosive environment, cast high-alloy stainless steel is used as tube material. Tube life is normally 2 – 3 years. Packed, brick-lined reactors are connected to the heating coil to provide additional residence time and housing for catalyst beds. Reaction takes place both in the tubes and in the reactors; almost all the hydrocarbons are converted by the time the gas leaves the last reactor.

Gas exiting the reaction furnace system passes through the sulfur condenser where most of the excess sulfur is separated. Next the cooled gas goes through a sulfur scrubber and then to the CS_2 scrubber in which the remaining sulfur is removed. The relatively sulfur-free gas then enters water-cooled condensers for bulk separation of carbon disulfide. The remaining carbon disulfide is finally removed from the hydrogen sulfide gas in the oil absorber. The hydrogen sulfide gas exiting the oil absorber contains 1 – 2 % methane and less than 1000 ppm carbon disulfide. This gas is routed to a Claus sulfur recovery plant where it is converted back to sulfur.

Crude carbon disulfide from the condensers, including that recovered in the stripper, is sent to the stabilizer column for removal of low-boiling impurities. The bottoms from the stabilizer column are next processed in the purification column where high-boiling contaminants are separated from the product. A caustic and water wash complete the product purification operations, and the finished product is pumped to check tanks and storage.

4.4. Other Processes

The use of different feedstocks for the manufacture of carbon disulfide is a subject of much economic interest. Raw materials evaluated include the following: methane and hydrogen sulfide [58], [59]; coke and coal with sulfur dioxide and hydrogen sulfide [60–62]; liquid hydrocarbons with sulfur [63–65]; hydrocarbons with sulfur and sulfur dioxide [66], [67]; chlorinated hydrocarbons and sulfur [68]; carbon monoxide and sulfur [36]; and organosulfur compounds with sulfur [69]. Most of these alternatives are unattractive because of poor yield, undesirable

byproducts, or difficulties in processing due to tar and polymer formation [70].

Important refinements to the basic methane process include the use of high-pressure (2000 kPa) condensation and fractionation for product recovery and purification [54], and modifications to the reaction furnace system to allow the use of olefinic feedstocks [71], [72].

5. Environmental Aspects

Carbon disulfide in the atmosphere is of biogenic as well as industrial origin [73]. Tropospheric concentrations of carbon disulfide have been reported as 3×10^{-5} ppm in remote areas and $7\times10^{-5}-30\times10^{-5}$ ppm in urban and industrial locations [74]. Natural release includes diffuse emission from soil [75] and volcanic eruption [73]. Industrial sources consist mainly of release from gasification and pyrolysis of carbonaceous fuel in the presence of sulfur compounds, from sulfur recovery (Claus) plant tail gas, and from industrial users of carbon disulfide [73], [74].

Investigations on the fate of carbon disulfide in the atmosphere show that the principal oxidation products are sulfur dioxide, carbonyl sulfide, and carbon monoxide [73], [76], [77]. Eventually these compounds degrade to carbon dioxide and sulfates.

Carbon disulfide may be removed from gas streams by oil absorption or adsorption with activated carbon [78], [79]. A common method used in the treatment of carbon disulfide and carbonyl sulfide in sulfur recovery plant tail gas involves hydrogenation and hydrolysis of these compounds to carbon dioxide and hydrogen sulfide. The hydrogen sulfide is then recovered by absorption in alkanolamine solutions [78], [80].

6. Quality Specifications and Analytical Methods

Carbon disulfide produced commercially in modern plants is generally of high purity and meets most of the specifications listed in Table 2.

Analytical methods for detecting carbon disulfide are detailed in references [83], [84]. A common procedure, sensitive to 1 ppm, is based on the reaction of carbon disulfide with diethylamine in the presence of a cupric salt to give the characteristic yellow cupric diethyldithiocarbamate. Infrared spectrophotometry is sensitive to 5 ppm, and gas chromatography can provide detection to 0.5 ppm.

Table 2. Carbon disulfide specifications [81–83]

Property	Grade		
	Commercial	ACS reagent	Viscose
Residue, %	0.002	0.002	0.01
Relative density *d*, 20 °C	1.261 – 1.265	–	1.260 – 1.270
Color, APHA	20	10	colorless
Dissolved sulfides			
lead acetate test	negative	–	–
mercury drop test	bright	bright	–
Sulfite and sulfate	–	0.002 % SO_2	–
Boiling range	46 – 47 °C	1 – 95 mL < 0.5 °C; 95 mL – dryness < 0.5 °C	98.5 % should distill between 46 and 47 °C
Water, %	–	0.05	–

7. Storage and Transportation [81], [85], [86]

The toxicity and extreme flammability and volatility of carbon disulfide make it one of the most hazardous chemicals to handle. Facilities using carbon disulfide must be designed to operate, at all times, as a closed system and above atmospheric pressure to avoid the influx of air. Whenever possible, these plants should be located outdoors or in open structures away from flames and other sources of ignition. Equipment should be properly grounded to prevent accumulation of static electricity. Water deluge systems around processing and storage areas should be provided; enclosed units should be designed with proper ventilation of the downdraft or lateral types.

Areas where appreciable concentration of carbon disulfide may be present should be designated as Class 1 hazardous locations as defined by the National Electrical Code [87]; electrical specifications should be in accordance with the requirements of the code.

Carbon disulfide is stored in properly diked above-ground steel tanks or in tanks confined in open-top water-flooded concrete pits. Underwater tanks are water padded, whereas water or inert gas padding is used in above-ground tanks. Transfer of carbon disulfide from storage tanks may be by padded pressure or pumps [81].

Carbon disulfide is classified by the United States Department of Transportation (DOT) as a Class 1 flammable liquid (identification number 1131). Use of the red label for flammable liquid is required. Transport of this chemical should follow DOT regulations [88].

8. Uses and Economic Aspects

In 1984, an estimated 1.1×10^6 t of carbon disulfide was produced worldwide in the following areas (production figures in 10^3 t/a):

North America	235
Western Europe	260
Eastern Europe	250
Latin America	50
Asia	160
Africa	10
Former States of USSR	120
Total	1085

In 1991 1.3×10^6 t of carbon disulfide was produced worldwide in the following areas (production figures in 10^3 t/a):

North and Central America	190
South America	54
Europe and Africa	822
Asia	221
Total	1287

[89]

The regenerated cellulose industry is by far the largest user of carbon disulfide. Over 65 % of world production is used in the manufacture of rayon (ca. 0.32 kg of carbon disulfide is consumed for each kilogram of rayon produced). Some 10 % is used in making cellophane, and another 10 % is chlorinated to form carbon tetrachloride (about 25 % of world carbon tetrachloride is produced by this method). The remaining 15 % is distributed among rubber chemicals, flotation agents, pesticides, and miscellaneous chemical reagents. Table 3 lists uses of carbon disulfide and some of its derivatives.

Table 3. Uses of carbon disulfide and its derivatives

Compound	Application	Reference
Carbon disulfide	reaction and extraction solvent, catalyst presulfidation agent, oil well solvent, cold vulcanization additive for rubber, synthetic chemical	[33], [81]
Sodium cellulose xanthate	precursor for rayon, cellophane, and regenerated cellulose products; chelating agent	[17]
Alkyl xanthates	flotation agent, lubricant additive, analytical reagent	[17], [83]
Carbon tetrachloride	fluorocarbon refrigerant, degreasing and cleaning solvent	[20]
Trichloromethanesulfenyl chloride	intermediate for fungicide and pesticide manufacture	[90], [20], [125]
Sodium, potassium, and ammonium thiocyanate	fungicide, electrolysis and electroplating solution additive, corrosion inhibitor, photographic emulsion stabilizer, metal complexing agent, fabric dye enhancer, herbicide, insecticide, soil sterilant, intermediate for pharmaceuticals	[91]
Dithiocarbamates	fungicide, insecticide, soil fumigant, herbicide and defoliant, rubber vulcanization accelerator	[33], [92], [93]
Thiocarbanilide	rubber vulcanization accelerator	[94], [95]
Benzothiazoles	rubber vulcanization accelerator	[94], [95]
Thiazolsulfenamides	delayed rubber vulcanization accelerator	[95]

Historical production and price data in the United States are shown in Table 4. Competitive pressure from synthetic fibers and films will continue to limit market growth in the regenerated cellulose industry. Improvement in carbon disulfide usage will be slow and must come from increased use in agricultural and specialty chemicals manufacture.

Table 4. United States carbon disulfide production and price

Year	$/t	Production, 10^3 t/a
1965	94	345
1970	97	330
1975	145	220
1980	240	170
1984	420	210

World production capacity for carbon disulfide is shown in Table 5. Excess capacity will continue in the United States and Europe.

Table 5. World production capacity for carbon disulfide, 1000 t/a, 1984∗

Area	Charcoal process	Methane process

9. Toxicology and Occupational Health

The toxicology data base on carbon disulfide is extensive. Citations include hundreds of experimental investigations on animals and many clinical and epidemiological reports on humans.

Mutagenicity and Genotoxicity. The mutagenic and genotoxic potential of carbon disulfide has been evaluated in vitro and in vivo [97–100]. Carbon disulfide does not exhibit mutagenic activity in bacteria (*S. typhimurium* and *E. coli*) with or without the presence of an activation system. Additional in vitro tests, including host-mediated assay, unscheduled DNA synthesis in human fibroblasts, and primary cultures of human leukocytes, are inconclusive [101], [102].

However, the significance of these tests cannot be properly evaluated because of methodological problems including the lack of proper positive controls. Therefore, insufficient data are available to evaluate the mutagenic and genotoxic potential of carbon disulfide.

Human Health Effects. Carbon disulfide toxicity in humans is well-documented in the literature. It was first recognized as a workplace hazard by the French in the 1850s. Subsequent studies demonstrated effects on the central and peripheral nervous systems and cardiovascular system. Carbon disulfide can induce polyneuropathy and encephalopathy. Poisoning may be acute or chronic.

Symptoms of polyneuropathy include paresthesia, cramps, muscle weakness, pain, distal sensory loss, and neurophysiological impairment [103–110]. Exposure to high levels of carbon disulfide for prolonged periods is necessary to produce the polyneuropathy. However, exposure at levels of 65 – 170 ppm for less than 1 year are reported to result in many of the symptoms described [103]. *Symptoms of encephalopathy* may include headache, sleep disturbances, general fatigue, loss of libido, impotence, organic dementia, and Parkinsonism [103–110]. Onset of symptoms range from several months to several years. The early stage of encephalopathy is characterized by depression with sudden attacks of hallucinations. Visual disturbances that may result from high levels of carbon disulfide exposure include abnormal color vision, loss of visual acuity, loss of accommodation, and retinopathy [111].

Cardiovascular alterations in humans may also result from carbon disulfide exposure. A number of studies [112–114] reveal vascular atherosclerotic changes following long-term exposure to carbon disulfide (30 – 90 mg/m^3). Below 10 ppm, cardiovascular effects are not apparent.

The toxic effects of carbon disulfide require that precautions should be taken to limit exposure in the workplace. In the United States, the TLV-TWA as adopted by ACGIH for exposure to carbon disulfide is 30 mg/m^3, 10 ppm [115]; the MAK value is the same. The federal standard (OSHA, 1985) is 60 mg/m^3.

Disposition. The primary route of human carbon disulfide exposure is inhalation. Uptake in the blood is rapid and carbon disulfide is transported to tissues. Carbon disulfide possesses significant lipophilicity while also binding to proteins and amino acids. In humans, most ($>$ 70 %) of a systemically absorbed dose is rapidly converted to metabolites, followed by urinary excretion. Less than 30 % of carbon disulfide is exhaled and very small quantities are excreted unchanged [116].

Subchronic Toxicity. A 90-d inhalation toxicity study using Fischer 344 rats, Sprague-Dawley rats, and $B_6C_3F_1$ mice (exposed simultaneously in the same chambers) was conducted with carbon disulfide vapor [117]. Evaluation of the hematology examinations (Fischer 344 and Sprague-Dawley rats) indicated effects on red cells and platelets. In addition, high-dose animals of both sexes exhibited a mild increase in neutrophils and a decrease in lymphocytes. Serum chemistry examinations at the high dose did not reveal dramatic changes. Organ weight data revealed a depression of brain as well as liver weight.

Histopathology studies revealed axonal swelling of spinal cord nerve fibers in high-dose males, high-dose females, and possibly mid-dose males. In addition, males and females from the high-dose group had segmental degeneration of fibers in the sciatic nerve. Other lesions that oc-curred were incidental and not related to treatment.

Biochemical Mechanisms. Understanding the mechanism of action of carbon disulfide toxicity may lead to early clinical intervention in cases of suspected poisoning. Although a number of hypotheses have been proposed, the biochemical mechanism(s) remain unknown. A metabolite of carbon disulfide may be responsible for its hepatotoxic effects [117], [118]. Sulfur is liberated during conversion of carbon disulfide to carbon dioxide. The liberated sulfur may bind to cellular components or critical enzymes, giving rise to toxicity.

Research has also focused on related areas, including the role of carbon disulfide in chelating dithiocarbamates, binding and depleting essential trace elements, disturbing vitamin

metabolism [73], turnover of catecholamines [119], and metabolizing lipids [120–122].

10. Carbonyl Sulfide

Carbonyl sulfide [*463-58-1*], carbon oxysulfide, COS, is a colorless, flammable gas that is sparingly soluble in water but very soluble in alcoholic alkalies [123]. Selected *physical properties* are:

M_r	60.07
mp	− 138.8 °C
bp at 101.3 kPa	− 50.2 °C
Heat of vaporization at 101.3 kPa	18.50 kJ/mol
Vapor density at 101.3 kPa, 25 °C	2.485 kg/m^3
Critical temperature	105 °C
Critical pressure	6179.4 kPa
Heat of formation at 25 °C	− 142.1 kJ/mol
Free energy of formation at 25 °C	− 164.3 kJ/mol

The chemistry of carbonyl sulfide has been reviewed [14], [123], [124]. *Production* of carbonyl sulfide may be by the reaction of carbon monoxide with sulfur [123], reduction of sulfur dioxide with carbon [62], or hydrolysis of carbon disulfide [21]. Small amounts of carbonyl sulfide invariably are formed when carbonaceous fuel is pyrolyzed in the presence of oxygen, steam, and sulfur compounds [78]; the removal of carbonyl sulfide from these gas streams is the subject of many studies [78], [80].

Carbonyl sulfide is widely dispersed in the earth's atmosphere; concentrations between 4.7×10^{-4} and 5.3×10^{-4}ppm have been reported [74]. Carbonyl sulfide has been suggested as a major causative agent in atmospheric sulfur corrosion [74].

The *commercial importance* of carbonyl sulfide is limited; it is not produced in large quantity, and is used principally for small-scale syntheses and experiments. The use of carbonyl sulfide as a raw material for chemical manufacture has been proposed [126].

Carbonyl sulfide appears to play an important role in mediating the *toxicity* of carbon disulfide. Carbon disulfide is metabolized in vitro [127] and in vivo [128] to carbonyl sulfide. Carbonyl sulfide is further metabolized by hepatic carbonic anhydrase to hydrogen sulfide [128].

Death from acute inhalation of carbonyl sulfide can occur within 45 min [129] at concentrations of 20 000 ppm. A single intraperitoneal injection of 50 mg/kg resulted in 100 % mortality. Presently, complete subchronic toxicity studies on carbonyl sulfide are unavailable. There is one report, however, describing effects following subchronic administration. Rabbits [112] were continuously exposed for 7 weeks to ca. 50 ppm COS. Within five days, three rabbits died and two were sacrificed in a moribund condition. There were no further mortalities. Cholesterol (serum) elevations were noted in exposed rabbits. Histopathology did not reveal changes in the lungs or in the intima of the arteries in the organs evaluated.

1. Introduction

The monoesters of carbonic acid can only be isolated as salts, simple anhydrides, or mixed anhydrides with carboxylic acids [1]. In the past, they have aroused little industrial interest. On the other hand, the symmetrical and unsymmetrical diesters derived from aliphatic and aromatic hydroxy compounds are widely used, especially as intermediates and solvents.

2. Properties

The industrially important dialkyl carbonic esters (**1**, R = alkyl) are all colorless liquids, and some of them have pleasant odors. Cyclic aliphatic and diaryl carbonic esters are colorless crystalline compounds with relatively low melting points, whereas cyclic aromatic carbonates have high melting points, up to almost 400 °C.

1

2

3

Most carbonic esters are insoluble or dimethyl- and diethylcarbonat sparingly soluble in water. Ethylene carbonate, 1,3-dioxolan-2-one **2** and propylene carbonate, 4-methyl-1,3-dioxolan-2-one **3** dissolve readily in water and are also soluble in organic solvents, particularly polar solvents. The other water-insoluble carbonates likewise dissolve in polar organic, solvents such as esters, ketones, alcohols, ethers, and substituted aromatic hydrocarbons.

The lower aliphatic carbonates form azeotropic mixtures with several organic solvents [2]. Dimethyl carbonate and ethylene carbonate form azeotropic mixtures with methanol and ethylene glycol, the alcohols from which they are respectively derived [3], [4].

Ethylene and propylene carbonates are extensively used as solvents for aromatic compounds, polymers, and saltlike compounds [5].

The physical properties of industrially important carbonic esters, including ethylene and propylene carbonate, are presented in Table 1. Properties of other cyclic carbonate, are listed in Table 2.

The ester structure and a strong tendency to form carbon dioxide play dominant roles in the chemistry of carbonic esters. Hydrolysis, which becomes more difficult with increasing molecular mass of the ester, leads to the formation of hydroxy compounds and carbon dioxide. Apart from massive steric effects, transesteri-

Diethylene glycol bis(allyl carbonate) [*142-22-3*]	− 4	160/0.27	1.143	1.4503	177 (open cup)
Diphenyl carbonate [*102-09-0*]	78.8	302/101.3	1.1215_4^{87}		168 (closed cup)
Ethylene carbonate [*96-49-1*]	39	248/101.3	1.3218_4^{39}	1.4158^{50}	
Propylene carbonate [*108-32-7*]	−48.8	242/101.3	1.2069_{20}^{20}	1.4189	

fication between carbonic esters and hydroxy compounds adheres to the following rule: the more nucleophilic hydroxy compound displaces the less nucleophilic compound, and if both hydroxy compounds have the same, or nearly the same, nucleophilicity, then the less volatile compound displaces the more volatile one. Hence, even with lower molecular mass alcohols, diaryl carbonates form dialkyl carbonates and the less nucleophilic phenols, but lower molecular mass dialkyl carbonates react with higher molecular mass alcohols to give the higher molecular mass dialkyl carbonates; the lower boiling alcohol is removed by distillation. In this case, transesterification occurs in steps with the intermediate formation of a mixed ester. The reaction of dialkyl carbonates with phenols to give diaryl carbonates, contrary to the above rule, can be achieved by using suitable conditions and catalysts [6]. It proceeds, however, at a relatively slow rate.

Carbonic esters react with primary and secondary amines to give urethanes and ureas [7]. At higher temperature and in the presence of catalysts, aliphatic carbonates lose carbon dioxide and act as alkylating agents, e.g., for amines [8] and phenols [9]. Rapid oxyethylation can be achieved in this way by using five-membered cyclic carbonates [10]. In the absence of compounds to be alkylated, these cyclic carbonates can be broken down to oxiranes and carbon dioxide, which is the reverse of the formation reaction [11]. Aliphatic and aromatic cyclic carbonate can easily be polymerized to a variety of homopolymers and copolymers with high molecular masses [12–15], [17–22]. Open-chain carbonic esters can be broken down catalytically at high temperatures to form alcohols, carbon dioxide, and olefins [23]. Dialkyl carbonates undergo Claisen condensation, e.g., with aliphatic carboxylic esters to form malonates [24].

3. Production

Carbonic esters have attracted increasing attention and been the focus of intensive research since ca. 1975 [25]. Figure 1 presents an overview of the various routes for producing carbonic esters and some important associated reactions. Carbon dioxide is the least expensive feedstock but also has the lowest reactivity, and it must therefore be transformed into more reactive compounds such as urea and cyclic carbonates. Although CO_2 can add to alcohols to form hemiesters, these are only present in low concentrations and, on account to their instability, their conversion to the diesters could not yet be achieved satisfactorily.

To avoid intermediate stages, the more expensive carbon monoxide is used. Either carbonic acid esters are formed by direct oxidative carbonylation of oxalic diesters which transform into carbonic esters by decarbonylation. Oxidation is performed with oxygen, if necessary via the nitric acid ester stage, or electrochemically. The latter technique, however, is still in its infancy.

For other methods of synthesizing carbonic esters, see [1], [26, p. 956, 964 – 966], [27].

3.1. Phosgenation of Alcohols

The phosgenation of hydroxy compounds is currently the most important method for producing

Table 2. Properties of cyclic carbonic esters

Ester		CAS no.	*mp*, °C	*bp*, °C/*p*, kPa

Figure 1. Synthetic routes to carbonic esters

carbonic esters [28]. Diethyl carbonate (DEC), one of the most frequently used aliphatic carbonates, is produced by passing gaseous phosgene in boiling ethanol, in a molar ratio of 1 part of phosgene to 2.5 – 4 parts of ethanol, into a glass or enamel apparatus consisting of a heatable reaction vessel with a reflux condenser and a distillation setup. The reaction gives essentially quantitative yields (≥ 99 %) and also forms hydrogen chloride. Excess ethanol is removed from the reaction mixture by distillation, and DEC is obtained as the residue.

To recover high purity (≥ 99.8 %) DEC that is free of chlorine (≤ 10 mg/kg), the crude product is distilled. If necessary, a base such as an alkali or alkaline earth metal carbonate, is used in the distillation. The yield based on phosgene is ≥ 95 %.

Dimethyl carbonate (DMC) is formed by the reaction of MeOH with phosgene or methyl chloroformate in the presence of a concentrated sodium hydroxide solution in a two-phase reaction in high yields and purity [29]. Other alcohols can also be phosgenated [30–32], [26, p. 953], [33–35]. As DMC is now more easily accessible via the direct oxidative carbonylation of MeOH, phosgenation is losing its attractiveness in this application.

3.2. Phosgenation of Phenols

Although diphenyl carbonate (DPC) produced by the oxidative carbonylation of phenol [36–38], the technology for this reaction has not yet been optimized. For this reason, the familiar [39–41] process of phosgenation of phenol has been subjected to renewed scrutiny with a view to improving the process and product quality (Cl-free). For example, phosgenation of aqueous sodium phenolate in the presence of DPC as solvent for newly formed DPC [25], [42] gave a high yield. Dissolving the phosgene in toluene before it enters the reaction vessel is said to increase safety, reduce costs, and minimize the Cl content of the DPC [43–45]. New purification methods have also been developed, e.g., rinsing with hot water and distillation [46].

From an early stage, there was interest in a homogeneously catalyzed phenol phosgenation process [47], [48] to avoid the formation of salts. The catalysts included salts of Al, Ti, Sn,

Zn, and Fe [48–52]; quaternary ammonium salts [53]; heterocyclic N bases [47]; and hydroxypyridines [54], [55]. The reaction rate (phosgene consumption) was highest at 130 – 150 °C [52], presumably because the increasing conversion of phosgene and its decreasing solubility with temperature are at an optimum in this range. Phosphorus compounds [56], [57] and higher alkylpyridines [58] make it possible to stop the phosgenation of phenol at the chloroformate stage. With other catalysts, such as certain salts of the alkali, rare earth, and alkaline earth metals, and metal oxides of Groups 2 and 12, phenyl chloroformate undergoes disproportionation to yiel DPC and phosgene. Further reaction with PhOH to yield DPC is also possible at higher temperatures, e.g., in the presence of phosphorus compounds [59], [60].

For this reason, a little more phenol is added at the end of the reaction to further lower the phenyl chloroformate content [45]. After rinsing with alkali and distillation, Cl-free DPC is obtained [61].

The need to separate homogeneous catalysts, usually by complex methods, led to a search for heterogeneous catalysts, including polymer-bonded pyridines [62] and phosphines [59], [60], activated carbon [63], metal salts on inert carriers [64], aluminum oxides [65], which had previously been considered inert, alumosilicates [66], silicates of various metals [67], and oxides of metals of Groups 2 – 5 [68], [69], ceramic precursors such as carbides, borides, nitrides [70], [71], and metallates of the metals of Groups 3 – 14 [70], [71].

Phenol phosgenation can be carried out in the liquid phase and in the gas phase [72] in a fully continuous reaction at 250 – 350 °C that gives almost complete phosgene conversion [73]. Complete phosgene conversion is also achieved by using an adiabatic procedure on a solid-bed catalyst, e.g., γ-Al_2O_3. The result is high-purity DPC in excellent yield and an electrolyzable hydrochloric acid [74–76], that is virtually no waste products (Fig. 2).

3.3. Oxidative Carbonylation of Alcohols

Homogeneous Catalysis. The reaction of alcohols with CO and oxygen to form dialkyl carbonates would seem both economically and ecologically desirable. This is reflected in the work on this reaction since the 1960s [77–82] using various CO-binding metal salts with an oxidative catalytic effect. The focus eventually concentrated on copper chlorides in the presence of various additives. Under certain conditions [83], [84–89] palladium compounds generate oxalic esters, sometimes as mixtures with carbonic esters, and are more difficult to reoxidize.

For this reason, work concentrated on the Cu system [90–93]. Non polar aprotic solvents [90], [94–98], N-bases, onium salts and alkali and alkaline earth metal salts [99–112] as well as additions of salts of Pd, of ferrous metals and the rare earths, complexing agents, and weak acids [113–115] are said to accelerate the reaction and improve the selectivity.

Some of the catalyst systems are highly complex, unstable, and generally difficult to separate from the reaction mixture. It therefore made sense to concentrate only on the effective Cu compounds. Using just a slurry of copper chloride [116], [117–120] in MeOH, it was possible to develop a workable DMC process with almost full selectivity for MeOH and 80 % selectivity for CO. ENI in Ravenna has used this process to produce DMC since 1983 [116–119] (Fig. 3). The plant was originally designed with an annual capacity of 5000 t and was expanded in 1993 to ca. 12 000 t [328].

The reaction follows this simplified redox cycle.

The main by product is CO_2, along with small quantities of methyl chloride and dimethyl ether. Water in high concentrations disrupts the reaction as it displaces MeOH from the Cu complex. However, small quantities (0.5 – 1 mol per mole Cu salt) accelerate the formation of DMC [120]. The loss of chloride as HCl and methyl chloride is countered by the addition of small quantities of $CuCl_2$ [121], HCl [122], [123], halogens, or oxidants [124], [125]. The obtained azeotrope-forming mixtures of DMC, MeOH, and H_2O can be separated by extraction distillation, the addition of azeotrope-breaking liquids, pressure distillation, and membrane separation processes [126–128], [129–133].

The sparingly soluble catalyst sediments poorly and can only be isolated for reuse by filtration. However, in a CO atmosphere, it quickly sediments in an easily separable form [134]. The catalyst can also be left in the reaction vessel if the feedstock streams and pressures are adjusted so that DMC, MeOH, and H_2O are removed and the quantity and concentration of feedstock and products in the reaction vessel remain constant [135–138]. With > 30 % DMC in the liquid output, DMC recovery is easier if the DMC/MeOH azeotrope can flow back into the reaction vessel. The CO, used in surplus, is also returned to the reaction vessel and freed wholly or partially from byproducts such as HCl, CH_3Cl, and CO_2 [139], [140].

Heterogeneous Catalysis. Oxidative carbonylation on insoluble or supported catalysts, primarily in the gas phase, was first investigated with copper chloride complexes applied to activated carbon [141]. The inadequate selectivity and stability were improved by the addition of alkali and alkaline earth metal salts, and regeneration with HCl was proposed [142]. Dow attempted to develop a process on this basis [143], with supports such as aluminum oxides, silicates, and zeolites [144–146].

Other supports are based on carbon or metal oxides with complex ligands, and with the addition of salts of alkali and alkaline earth metals, bases, and borates [147–159]. This resulted in selectivities of up to 90 % for CO and 99 % for MeOH and more stable catalysts.

An interesting variant is the copper chloride-catalyzed oxidative carbonylation of alcohols in a Cu_2Cl_2/KCl melt (120 – 180 °C), performed continuously in a type of distillation column. The melt is continuously removed, dewatered, and then returned to the column [160–162]. Very good selectivity is achieved at low conversion rates. The apparatus must be made from corrosion-resistant materials.

In contrast to copper chlorides, whether in solution or in the molten state, active cobalt complexes are noncorrosive and less sensitive to water. Ligands include, e.g., Schiff bases with salicylaldehydes, oximes, pyridines, phenanthroline, acetyl acetone, and oxyquinoline, and solvents are, e.g., amides, nitriles, sulfones, sulfoxides, carbamates, and ureas [163–165]. The catalysts can be applied to supports and used in the gas phase [166]. However, ligands which are stable to oxidation are as yet unavailable [167].

3.4. Oxidative Carbonylation of Phenols

Homogeneous Catalysis. Analogous to the oxidative carbonylation of alcohols, diphenyl carbonate (DPC) can be synthesized from PhOH and Pd compounds [36–38]. The reaction can be steered to yield DPC or phenyl salicylate [171–173]. Water has a far more disruptive effect here than in MeOH carbonylation and must be quickly rendered harmless by using molecular sieves [36], [168–170]. Important to the smooth process of DPC formation are N bases, especially sterically hindered bases, complex ligands for Pd, and suitable redox-active metal complexes, especially of Mn and Co [36–38], [168–178].

However, it is also claimed that it is possible to form DPC in the absence of bases [179], [180]. Instead of redox-active metals, iodides

[180] and benzophenones and quinones as cocatalysts [179], [181–183] are recommended. A catalyst system with a Co salicylaldimine complex, Pd acetate, terpyridine, hexaalkylguanidinium bromide, and an aprotic polar solvent such as N-methylpyrrolidone or DPC [184–186] accelerates the reaction while maintaining a selectivity of around 98 % with DPC contents of around 20 – 30 %. The selectivity decreases outside this range. Rare earth metal compounds, hydroxypyridines, and alkali or alkaline earth metal halides in aprotic polar solvents are also claimed to yield high selectivity [187], [188]. To ensure reproducible results, the Pd catalyst must be pretreated and activated with CO [189].

Instead of using molecular sieves, which require laborious regeneration, the reaction water can be flushed out efficiently with excess CO, e.g., in serially arranged bubble columns or by continuous withdrawal, dewatering at reduced pressure, and recycle of a partial stream of the reaction mixture [190–192]. That all can be achieved at a Pd content of only around 260 ppm in the reaction mixture. If gas throughput, total pressure and partial pressures of the reaction gases are kept constant, the space – time yield increases [193], [194].

The following byproducts of oxidative carbonylation have been identified: salicylate [171–173], *o*-phenylene carbonate and bromophenols [195], and phenoxyphenol [196]. The addition of Co compounds is claimed to completely suppress the bromination of PhOH [197].

Heterogeneous Catalysis. If the oxidative carbonylation of phenol is to be brought to technical maturity, a simple and continuous mode of operation and work-up, full catalyst recovery and regeneration, a heterogeneous catalyst, and efficient DPC purification must be developed. Various proposals have been made.

The reaction can be performed continuously in a multiplate rectification column [198] with side feeds to several reaction vessels that are also supplied with reaction gas. The reaction mixture is then returned to column at a point above which it was removed [199]. A bubble column cascade also allows continuous operation [190–192].

The DPC can be removed from the reaction mixture by vacuum distillation [200], but this will results in thermal damage to the catalyst system. However, the use of crystallization processes, perhaps in combination with distillation, minimizes this damage, and the catalyst can be recovered in a usable form [201–206].

Another mild method is to extract DPC from the reaction mixture with certain solvents [207]; the catalyst remains in the phenolic phase. Both this method and crystallization are benefited by a high DPC content in the reaction mixture [208]. The deactivated catalyst can be regenerated by oxidation [209].

It is difficult to convert complex systems like the ones used here into efficient heterogeneous catalysts. For this reason, work began with supported Pd [210], [211]. The addition of CsBr or nitriles to the reaction mixture had a favorable effect. Pd and Cu compounds with hydroxypyridine on activated carbon gave high selectivity for CO [212]. In other cases, activated carbon was simply added to the system, and considerable DPC yields were achieved [213], [214].

Insoluble oxides, nitrides, and carbides act as promoters [215]. It is possible to fix Pd and cocatalysts on supports as highly active products with long-term stability and thus develop a continuous process of DPC synthesis including DPC isolation and the recovery of the mother liquor [216–219].

3.5. Oxidative Carbonylation of Alcohols with NO_x

Palladium compounds, valued because of the mild carbonylation conditions, are easier to reoxidize with nitrites than with O_2 and alkyl nitrites are simple to manufacture. Hence, this route was investigated for DMC synthesis [220–223]; the reaction is ideally performed with heterogeneous Pd catalyst in the gas phase. Depending on the reaction conditions and the catalyst used, carbonates and/or oxalates are formed [224], [225].

To improve the selectivity for DMC, various catalyst supports such as aluminum oxides, metal phosphates and, in particular, zeolites [226–231] were investigated. These were doped with heavy metal, alkali and alkaline earth, and nonmetal compounds [232–234] and special ligands for Pd [235–237]. Chlorinated compounds are used to regenerate the catalysts [238–241]. The resulting systems have outstanding stability and selectivity, with particular interest attracted

by the Pd/Cu catalysts [242–245]. Concepts for a complete process were developed [246–251]. At the end of 1992, Ube started a DMC plant with a capacity of 3000 t/a using this process. Expansion to several tens of thousands of tons was planned [252].

$$CO + 2\,CH_3ONO \longrightarrow CH_3OC(=O)OCH_3 + 2\,NO$$

$$2\,CH_3OH + 2\,NO + 1/2\,O_2 \longrightarrow 2\,CH_3ONO + H_2O$$

3.6. Carbonic Esters from Oxalic Esters

Alcohols react with CO and O_2 or alkyl nitrites under certain conditions [84–89], [224], [225], [253–255] with highly selective formation of dialkyl oxalates. It would therefore seen obvious to exploit this CO fixation in carbonate synthesis, namely, by transesterifying dimethyl oxalate with PhOH to form diphenyl oxalate, followed by decarbonylation.

$$2\,CO + 2\,CH_3ONO \longrightarrow CH_3OCOCOOCH_3 + 2\,NO$$

$$CH_3OCOCOOCH_3\ 2\,PhOH \rightleftarrows PhOCOCOOPh + 2\,CH_3OH$$

$$PhOCOCOOPh \longrightarrow PhOCOOPh + CO$$

This transesterification requires conditions and catalysts similar to the manufacture of DPC from DMC and PhOH [256]. Diphenyl oxalate can be isolated and purified via a 1 : 2 adduct with PhOH [257]. The decarbonylation of diphenyl oxalate takes place at high temperatures and is catalyzed by heavy metal, alkali, alkaline earth, rare earth, and nonmetal compounds from Group 15, especially P compounds [258–265], with selectivities of up to 99 % and DPC yields of up to 96 %. Decarbonylation can also be carried out in the gas phase [266–268]. Concepts have been developed for transesterification, decarbonylation, and an overall process [269–271].

3.7. Electrochemical Oxidative Carbonylation of Alcohols

The oxidative carbonylation of alcohols is also possible at the anode of a suitable electrochemical apparatus [272–275]. High current efficiency can be attained but nothing is known about the cost – benefit ratio of this process.

3.8. Reaction of CO_2 with Oxiranes

The catalytic reaction of CO_2 with oxiranes directly yields five-membered cyclic carbonates (dioxolanones). Transesterification with alcohols allows the synthesis of other carbonates from inexpensive CO_2. The byproducts are 1,2-diglycols, especially ethylene glycol (EG), which is produced in enormous quantities worldwide by hydrolyzing ethylene oxide (EO) [16]. This process provides EO and EG producers with economical access to carbonic acid derivatives by using CO_2 from EO synthesis. The reaction of CO_2 with oxiranes, especially EO and propylene oxide, takes place under pressure with catalysts such as alkali metal iodides, ammonium and phosphonium salts, Lewis acids, heavy metal complexes, organometallic compounds, and ion exchangers with ammonium or phosphonium groups [276–281], [26], [282], [283]. Under milder conditions, the reaction takes place in the presence of bifunctional catalysts such as pairs of alkali metal and zinc halides [284], [285] and affords very high selectivity. A new process has been developed using this type of catalyst in which EO and CO_2 in EC as the reaction medium are converted under mild adiabatic conditions to EC in high yield. After purification, the quality of the product is excellent [284–289] (Fig. 4).

The combination of CO_2 and EO to form EC is reversible in the presence of the above-mentioned catalysts and others [290].

Like EO, other oxiranes can be converted into dioxolanones by reaction with CO_2 [291–293].

3.9. Reactions of Alcohols with Urea

At elevated temperatures, ammonia is gradually displaced from urea by alcohols, initially forming carbamates and then carbonates [294–296]. Depending on the temperature and the duration of the reaction, the two steps can be performed separately and both carbamates and carbonates obtained in high yields (98 %) [297–299]. Both

Figure 4. Production of EC from EO and CO_2 [286]
a) Reaction vessel, adiabatic; b) High-speed evaporator with heating jacket; c) Heat exchanger for steam generation; d) Depressurizing; e) Catalyst regeneration.
RM = Reaction mixture

reactions are catalytic. Nitrogen bases and salts, oxides, hydroxides, and alkoxides of alkali, alkaline earth, and many heavy metals, especially Sn, have been suggested as catalysts. High-boiling solvents are claimed to accelerate the reaction [298], [299]. Unfortunately, the reaction is virtually limited to higher alcohols, yet this route can be used to produce DMC by first reacting 1,2- or 1,3-diol with urea to form a cyclic carbonate (e.g., EC), followed by treatment with MeOH to form DMC [300], [301]. In both these steps, the selectivity is 95 – 99 %. As this synthesis always yields large quantities of ammonia as byproduct, it should preferably be located near a urea manufacturing facility.

3.10. Reaction of Phenols with Urea

The reaction of PhOH with urea generates NH_3 but little DPC [302]. Cyanic acid, formed above 130 °C, is quickly taken up by nucleophilic alcohols to form carbamates. However, this does not apply to the weakly nucleophilic PhOH and the cleavage of urea results in the usual derivatives of cyanic acid. To obtain DPC, the PhOH must be treated with urea intermediates such as DMC or urea derivatives of less nucleophilic and volatile amines than NH_3. Thus, diphenyl urea yields diphenyl carbamate and DPC [303].

3.11. Miscellaneous Reactions of CO_2 to Form Carbonates

Although technically interesting, less work has been done on the reaction of CO_2 with olefins to form dioxolanones [304–306] in the presence of oxidizing metal ions such as $Au^{(III)}$ and $Tl^{(III)}$, and on the addition of CO_2 to prop-1-yn-3-ols to form 5-methylene-1,3-dioxolan-2-ones [307], i.e., five-membered cyclic carbonates, which can be transesterified with MeOH to yield DMC, and on the reaction of CO_2 with alcohols and their acetals, ketals or orthoesters [308–310] in the presence of Sn compounds, whereby acetals, ketals, ortho esters, and molecular sieves act as water scavengers and convert them into aldehydes, ketones, and esters that can be reused. In this context, EO could also be termed a water scavenger when treated with CO_2 and, e.g., MeOH, to form EG and DMC [311], [312].

In the presence of certain Cd, Mg, and particularly Zn catalysts CO_2 undergoes alternating copolymerization with cyclic ethers, especially EO, to give polycarbonates [313]. Carbon diox-

ide is therefore becoming increasingly attractive in industrial chemistry [314], [315].

3.12. Transesterification

Since transesterification is an equilibrium reaction, it is possible in principle to convert one carbonate into another. However, in practice, this may prove difficult, require special conditions, or even fail.

Transesterification of Ethylene and Propylene Carbonates with Alcohols. Transesterification with EC runs particularly smoothly and quickly [316], [317]. Because of the significance of DMC, much work has been carried out on its synthesis, and the results have also been applied to carbonates of other alcohols. A wide variety of catalysts have been proposed [318]: alkali and alkaline earth metals as salts, oxides, and bound to ion exchangers [319–326], heavy metal compounds [327–334] rare earth compounds [335], [336]; N and P bases, their quaternary salts, and anion exchangers based thereon with various cations, especially those of weak acids [337–345]; derivatives of Ti, Zr, and Sn [326], [346], [347]; and catalysts consisting of two metal salts or of a metal salt and an onium salt which are highly effective in catalyzing the formation of EC from EO and CO_2 as well as transesterification [284], [285].

The course of the reaction is strongly dependent on the choice of catalyst. In the transesterification with Dowex MSA-1, an anion exchanger in chloride form with ammonium groups, the DMC yield is 99 % at 48 % conversion. Amberlyst A-21, a very similar exchanger, gives a yield of only 92 % and 18 % conversion under otherwise identical conditions [348]. Another anion exchanger in carbonate form gave 45 % conversion and $>$ 99 % yield at a water content of less than 160 ppm, but only 5 % conversion with the same yield at a water content of 200 ppm [349].

The technical environment for transesterification also influences its cost-effectiveness. If EC and MeOH are reacted together in cocurrent flow on a fixed bed catalyst [350], [351] conversion at best corresponds to the equilibrium. Therefore a difficult separation of feedstock and products by distillation is required, for both EG with EC and DMC with MeOH form azeotropes which must be broken [3], [4], [126–133], [352–354]. Only great care in catalyst manufacture prevents leaching of the heterogeneous catalysts. Otherwise, the resulting contamination must be removed before distillation [355], [356]. Transesterification and separation can be carried out simultaneously in distillation columns. A heterogeneous catalyst is placed on the plates, and the dwell time in the column is extended by removing a sidestream and passing it through a reaction vessel. In the case of incomplete conversion, water is fed into the bottom of the column to hydrolyze the residual EC [357–359]. If the catalyst activity and the process parameters are properly balanced, counterflow transesterification in a column yields a distillate that contains more DMC than the MeOH/DMC azeotrope at the top of the column and a virtually EC-free EG at the bottom [360], [361].

Dimethyl carbonate can also be produced by other transesterification reactions, e.g., by methanolysis of Bisphenol A polycarbonate (recycling) [362].

Transesterification of Phenols with Aliphatic Carbonates. For the entirely phosgene-free manufacture of Bisphenol A polycarbonate, the DPC must also be produced in a similar way. This can be achieved by the transesterification of DMC as, under transesterification conditions, EC oxyethylates PhOH with decarboxylation. However, the reaction of DMC with PhOH is slow and, because of the weak nucleophilicity of PhOH, the equilibrium is almost entirely on the DMC side. It is therefore necessary to ensure that the equilibrium is achieved as quickly as possible by the use of very active catalysts with high selectivity and that the equilibrium is quickly shifted by suitable modes of operation. The reaction takes place in three catalytic steps:

Steps 1 and 3 are slower than step 2. However, it would seem more economical to favor step 3 over step 2, as the DMC already bound to the PhOH is otherwise lost again. There is only limited potential to accelerate the reaction by the application of higher temperatures as, from around 200 °C, etherification (anisole) and carboxylation (salicylic acid derivatives) reduce the selectivity. For this reason, the reaction conditions and the catalysts used must be balanced accordingly [6], [363], [364]. The most important catalysts are Lewis acids and complexes of Ti, Zr, V, Zn, Fe, and Sn [365–367], Pb compounds [368], [369], alkali and alkaline earth salts of silicic, boric, phosphoric, and orthotungstic acids [370], alkyl tin compounds and titanates [363], [364], [371–377], some of which develop excellent activity and selectivity. Oxides, mixed oxides, silicates, and phosphates of numerous metals [363], [364], [378–380] have been less widely investigated.

Due to the unfavorable kinetic and thermodynamic conditions, the transesterification of DMC to DPC requires the use of complex process technology. For example, the use of a continuous distillation column has been recommended, whereby DMC and MeOH are removed at the top, and the higher-boiling products at the bottom for further work-up [381], [382] as have a system of several serially arranged reaction vessels with a column setup where DMC is fed in at the base of the reaction vessels [383–385], and a combination of two continuous distillation columns, in which the second column receives the bottom product of the first, and the first column the head product of the second [386]. Here, one or both columns can be linked to reaction vessels by sidestream removal and return feeds [387–390]. To decrease the DMC content of of the distillate below that the MeOH/DMC azeotrope, the distillate containing the azeotrope can be passed a number of times in counterflow through a column to yield high-percentage MeOH [391]. In the case of the two-column system, the distillate containing DMC from the first column is passed into the second, and a high yield of phenyl methyl carbonate is obtained at the bottom of the second [392], and is then converted to DPC by disproportionation (Fig. 5).

However, the transesterification can be steered such that almost pure DPC is discharged at the bottom of the second column [394]. The same applies for a combination of a counterflow and a reactive distillation column, and a good DMC conversion is achieved [395].

Transesterification in bubble column cascades yields an outstanding space – time yield [396], [397].

Further steps are required to separate the catalysts [398], [399] and the byproducts from DPC [201–206], [208], [400–402].

Where acetic anhydride or ketene is available, the transesterification process can follow the sequence:

A number of variations are possible [403–409] which can be applied to bis-phenols to yield aromatic polycarbonates [410–413].

The direct transesterification of DMC with bis-phenols to form bis-phenol monomethylcarbonate and bis-phenol dimethylcarbonate or polycarbonate is more difficult [414–417].

DPC is also produced in a good yield by the phenolysis of aromatic polycarbonates (recycling) [418–420].

3.13. Cyclic Carbonic Esters

Cyclic carbonates can be produced in similar ways to the open-chain carbonates, i.e., by phosgenation [421–423], oxidative carbonylation [424] or transesterification [425–432] of dihydroxy compounds with, e.g., DMC, and also from urea [433–435]. However, these have the peculiarity that the main reaction product is usually a polymer or a mixture of monomers, oligomers, and polymers from which the monomers must be recovered by additional steps, usually by a combination of thermal degradation and distillation [436–438].

All aliphatic dihydroxy compounds react rapidly with phosgene to form bis-chloroformates, which with another diol in the presence of bases or at elevated temperatures are converted to the corresponding carbonates with cleavage of HCl. As working with bases pro-

Figure 5. PhOH/DMC transesterification to methyl phenyl carbonate (MPC) [392]
a) Reaction distillation; a1) Reaction; a2) Rectification; b) Rectification; c) Flash distillation

duces large quantities of salts, the latter method is preferred [423], although small amounts of chlorinated byproducts are formed which are sometimes difficult to remove. For this reason, transesterification is the method of choice for producing high-purity carbonates [439]. Until now, oxidative carbonylation has been of little significance here. Transesterification can be carried out with aliphatic carbonates, especially DMC and DEC, but also with EC and DPC, the latter being recommended if working with diols having high melting points and at higher reaction temperatures as the melts are otherwise too viscous [440].

This process is used to manufacture cyclic carbonates from, e.g., 1,3-propanediol [425–435], 1,4-butanediol [425–432], 1,6-hexanediol [433–435], diethylene glycol [425–432], triethylene glycol [425–432], neopentyl glycol [423], [425–435, 439], pentaerythrite [425–432], trimethylol propane [425–432], [440], glycerin [425–432].

Cyclic aromatic carbonates can be produced above all by phosgenation and transesterification of, e.g., Bisphenol A [441–445], *o,o′*-dihydroxybiphenyl [446], 2,2′-dihydroxy-1,1′-bisnaphthalene [447], bis(2-hydroxy-3-cycloalkyl-5-alkylphenyl) alkanes [448], bis(2,4-dihydroxy-3-methylphenyl)methane [449], various tetraphenols [449–452].

4. Environmental Protection and Toxicology [453–456]

The safety precautions taken when working with phosgene must be taken during the normal production of carbonic esters. The exhaust gases are subjected to hydrolysis and then burned. Wastewater is freed of all undesired substances, e.g., phenol, by extraction and desorption.

Although carbonic esters are not generally considered dangerous substances, they must not enter the atmosphere or the water supply. Vapors must be removed by adequate exhaust systems, and spilled liquids must be absorbed onto an appropriate material, which is subsequently burned.

All important carbonic esters are flammable substances. In particular, the short-chain, aliphatic esters can be easily ignited because of their low flash points. Carbonic esters form explosive mixtures with air.

Handling precautions:

Eyes:	Safety goggles or face shield
Skin:	Protective clothing and gloves
Inhalation:	Adequate and effective ventilation
Ingestion:	No eating, drinking, smoking during handling

First aid:

Eyes:	Rinsing with plenty of water for least 10 min, consult physician
Skin:	Removal of contaminated clothing, washing with plenty of water, consult physician
Inhalation:	Move to fresh air, call physician
Ingestion:	Vomiting if conscious, immediately to hospital or physician

Toxicological Data.

Diethyl carbonate

LD_{50} (s.c.)	8500 mg/kg (rat)
LD_{50} (oral)	> 5000 mg/kg (rat)
TDL_0	500 mg/kg (mouse)
LC_{50} (inhalation)	> 21 mg/kg (mouse)

No irritation after contact with skin or mucous membranes (rabbit).

Dimethyl carbonate

LD_{50} (oral)	12.9 g/kg (rat)
LD_{50} (intraperitoneal)	1600 mg/kg (rat)
LD_{50} (cutaneous)	2500 mg/kg (rat)
LC_{50} (inhalation)	140 mg/L (4 h, rat)

Irritation possible after contact with skin and especially eyes.

Diphenyl carbonate

LD_{50} (cutaneous)	> 500 mg/kg (rat)
TDL_0 (oral)	28 g/kg (mouse)
TDL_0 (s.c.)	1000 mg/kg (mouse)

Prolonged and repeated skin contact can cause irritation and dermatitis. Prolonged inhalation of dust can irritate and affect the respiratory tract.

Ethylene carbonate

LD_{50} (oral)	10 g/kg (rat)

Inhalation of vapors (8 h, rats) does not cause death.

Propylene carbonate

LD_{50} (oral)	29 g/kg (rat)

Diglycol bis(diallyl carbonate)

LD_{50} (oral)	349 mg/kg (rat)
LD_{50} (cutaneous)	3038 g/kg (rabbit)
LC_{50} (inhalation)	> 0.73 mg/L (1 h, rat)

5. Quality Specifications

Carbonic esters are isolated in pure form by distillation. Dialkyl carbonates of ≥ 99.6 % purity are obtained as colorless liquids, free of water and containing less than 0.05 % Cl. DPC of 99.9 % purity, recovered in the molten state, has a color index of 20 – 30 (APHA) and a maximum phenol content of 0.05 %. If it is produced by transesterification of PhOH and DMC, there may be traces (≤ 0.1 %) of phenyl methyl carbonate.

Diethylene glycol bis(allyl carbonate) is more than 94 % pure, contains ≤ 1 % volatiles ($< 150\,°C$/5 mm Hg), has a color index of ≤ 30 (APHA), and a viscosity at 25 °C of $\leq 22 \times 10^{-6}\ m^2/s$.

6. Analysis

Gas chromatography is the simplest and most efficient method of analysis applicable to most impurities in carbonic esters. Titrations are used to detect water and traces of hydrogen chloride. Chloroformate can be detected by titration or gas chromatography [457].

7. Storage and Transportation

Because carbonic esters are not corrosive they can be stored, in the absence of moisture, in stainless steel tanks for at least one year. DPC can be stored in the molten state at 150 °C for approximately one month. However, allyl carbonates can only be stored for a limited time because of their tendency to polymerize. The permissible period of storage depends primarily on the temperature. Dialkyl carbonates are transported in steel barrels or tank cars. DPC is delivered as flakes in polyethylene sacks or in the molten state in tank cars.

8. Uses

8.1. Direct Uses

All of the main simple carbonates – DMC, DEC, EC, PC and even DPC in the molten state – are excellent solvents for a variety of substances such as cellulose ethers and esters [26], [454–456], pharmaceutical and cosmetic preparations [458–465], natural and synthetic resins and polymers [5], and salts. They serve as extractants [466–469], plasticizers, spinning dopes for

synthetic fibers, electrolytes [466–475], and additives for cleansing agents [476]. The addition of DMC improves the phenol yield when hydrocracking tar [477]. It also has a positive effect on fuel combustion [478–481] and as a foaming agent [482], [483]. Higher carbonates and cyclic aliphatic carbonates are used in the formulation of flavors and fragrances [484–486], and certain cyclic aromatic carbonates for thermal recording materials [487]. Cyclic carbonates are also used as reactive thinners in RIM polyurethanes [488], as activators in polyurethane coatings [489], epoxy [490], [491] and phenol – formaldehyde resins [492], and in silicate-based binders for molding sand [493]. Further applications are described in [466–469, 494, 495].

8.2. Use for Chemical Synthesis [1], [26], [496–501]

Transesterification. The transesterification of EC or DMC with aliphatic diols can be turned to aliphatic polycarbonates with certain molecular masses and OH numbers for the manufacture of polyurethanes [502–504]. Oligocarbonates based on $C_{12} - C_{44}$ alcohols and triethylene glycol yield high-quality lubricants and additives [505–508]. The carbonates of oximes or cholines with DPC are used as intermediates for bleaching and cleansing agents, and those of specially substituted phenols and alkynols for crop protection products [509–514], [515], [516].

Unsymmetrical carbonates can be produced from alcohols and symmetrical carbonates or from two different symmetrical carbonates [517–519], and monomethylcarbonates of dihydroxy compounds [520], [521] from DMC and the corresponding diols. Because of the outstanding properties, particularly of optical plastics made from allyl and vinyl carbonates, these are produced in various forms with particularly high purity by the transesterification of diols, allyl alcohol, and vinyl esters with DMC [393], [522–529].

Of major significance is the transesterification of bis-phenols, especially Bisphenol A, with DPC to form high-quality thermoplastic aromatic polycarbonates [530], [531]. Attempts have also been made to produce these polycarbonates with DMC or DEC as the CO donor, either by direct transesterification [532–534], stepwise by first synthesizing a Bisphenol A bis(methyl carbonate) and then reacting this with itself [535–537] to split off DMC, or by reaction of Bisphenol A diesters such as BPA diacetate with DMC, splitting off methyl acetate [538], [539]. Polycarbonate synthesis is achieved in all these cases, but none have gained industrial significance, presumably, secondary reactions result in unsatisfactory reproducibility.

The hydrolysis of EC produces a very pure EG in almost quantitative yield [277]. By comparison, EO yields 82 – 85 % EG and also polyglycols.

Alkylation. Nucleophilic substances are alkylated by DMC with CO_2 elimination. These substances include phenols, thiols [9], [540–548], amines [8], [549], [550], amides and urethanes [551], [552], alcohols [553–555], even if these contain trialkylamino groups (i.e., usually, under similar conditions, the trialkylamino groups are quaternized and/or split off, but not in this case) [556], [557], and carboxylic acids and their anhydrides [558–562]. In all cases, the corresponding carbonates are produced, often as isolable intermediates, which split off CO_2 under more extreme conditions. In this way, DMC can be used to form methyl ethers, amines, amides and esters, DEC the ethyl compounds, EC the hydroxyethyl compounds [10], and diallyl carbonate the corresponding allyl compounds. DMC and DEC also react with SiO_2 and TiO_2 in the presence of alkali hydroxide in a solid-gas reaction at 250 – 350 °C to form $Si(OCH_3)_4$, $Si(OEt)_4$, $Ti(OCH_3)_4$ and $Ti(OET)_4$ [563–566] in high yields.

Ethylene carbonate is often preferred to ethylene oxide for oxyethylation reactions because it is much easier to handle.

DPC and substituted DPC reacts analogously with, e.g., terephthalic acid to form its diphenyl ester and 4,4′-dinitrodiphenyl carbonate, which is converted to the 4,4′-dinitrodiphenyl ether and CO_2 at higher temperatures (risk of explosion).

Cyclic carbonates eliminate CO_2 catalytically to form cyclic ethers such as oxiranes, oxetanes, dioxanes, crown ethers, etc. by intramolecular alkylation [11], [567–570].

Active CH bonds are alkylated by carbonates, with substitution of the H atom by the alkyl group. Examples are phenylacetonitriles, phenyl

acetates [571], butyrolactone [572], malonic diesters [24], and acetoacetic esters.

Catalysts for the alkylation are bases, e.g., alkoxides, K_2CO_3, 4-dimethylaminopyridine, quaternary ammonium salts, platinum group salts, aluminum oxides, basic Mg compounds, and SnO. The reactions usually run smoothly and produce excellent yields, with CO_2 and the feedstock alcohol as the byproducts. These can be easily recovered for reuse. The same also applies to the other reactions discussed here, which is the reason for the strong growth in interest from industry in the chemistry of carbonic esters. Many of the substances produced by these alkylation processes are commercial products that are often still produced with other alkylation agents, some of which are toxic and produce salts.

Carboxylation. Under mild conditions in the presence of equivalent quantities of strong bases, active CH groups react with carbonates to yield carboxylic esters. This applies to substances such as ketones, nitriles, aliphatic nitro compounds and esters, which form, e.g., malonic esters [314], [315], [496–501].

Further considerable potential is provided by the transformation of amines to ureas and, in particular, urethanes. Both groups yield substances for crop protection [573], [574], pharmaceutical preparations [575], [576], and, by reaction of amines with EC [577], [578] lubricant additives [579]. The methyl isocyanate required for the synthesis of crop protection products is obtained by treating DPC with methylamine to form methyl phenyl urethane for cleavage [580], [581]. Bayer and ENI manufacture methyl isocyanate in this way.

The reaction of diamines with carbonates to form bis-urethanes and diisocyanates for polymers has been the focus of a great deal of work, since high selectivity and very high purity are required. Catalysts for urethane formation are Co complexes, organotin compounds, zinc salts and in α-position branched carboxylic acids [582–584], lead, titanium and zirconium derivatives [585–587], which also catalyze the reaction of ureas with carbonates to form urethanes. The secondary reactions of alkylation are virtually excluded, especially when working with Ti alkoxides and zinc acetate.

Diarylphosphinic acid is claimed to be an excellent catalyst for the reaction of DPC with aromatic amines [588]. Aliphatic mono- and diamines react virtually quantitatively with DPC, even under mild conditions, to yield *O*-phenylurethanes, which can be cleaved easily to yield isocyanates [589], [590]. The corresponding reaction with DMC to form *O*-methylurethanes requires catalysis with alkali metal alkoxides [591]. Daicel and Degussa-Hüls plan to use this process in the joint production of isophorone diisocyanate for polyurethane coatings.

Cyclization. Analogous to the reactions of diols to yield cyclic carbonates, many other compounds with two reactive groups such as 2-aminoalcohols, α- and β-hydroxycarbonamides, malonic diamides, 1,2- and 1,3-diamines yield known heterocyclic substances which are used in pharmaceutical and crop protection applications [592]. It is even possible to cyclize polyamidic acids to form polyimides [593].

Pyrolysis. Heating longer chain carbonates to $>300\,^{\circ}C$ yields olefins. ω-Hexenol is distilled off from hexanediol-1,6-polycarbonate, and methanol, CO_2 and ω-decenol (an insect attractant [23] in ca. 75 % yield) from 1,10-decanediol monomethyl carbonate.

At much lower temperatures, methanol and CO_2 are split off from the methyl carbonates of the β-hydroxyethyl compounds with the structure $HO–(CH_2)_2–X$ (X = N, S, O, P), which are easily produced by oxyethylation, evidently benefited by the neighboring group effect. This provides access to easily polymerizable vinyl phosphonates, *N*-vinyl heterocyclene [594–596] and *N*-vinylphthalimide [13], [597] for flame-resistant polymers and special ion exchangers.

Polymerization of Cyclic Carbonates. The aromatic cyclic carbonates produced from the bis-phenols, especially those produced from Bisphenol A, polymerize in the presence of many catalysts to form thermoplastics with medium to very high molecular masses and very high quality [12–16]. Compounds with two carbonate rings can be used for branching and achieving flame resistance [598]. Depending on their structure, other aromatic cyclic carbonates undergo statistical or block copolymerization with cyclic Bisphenol A carbonates to yield thermoplastics with high glass transition tempera-

tures [599], [600]. An unsymmetrical cyclic carbonate yields an optically active polycarbonate [601].

A wider variety of options are offered by the polymerization of aliphatic cyclic carbonates [602]. Catalyzed with cationic, anionic, or organometallic compounds, in solution or in the molten state, they form copolymers with widely differing properties and, in some instances, very high molecular masses [17–22]. Lactams yield copolymers which, depending on the monomer content, contain urethane, amide, ester, and carbonate groups and can be used to improve the flow properties in the melt and increase the notch impact resistance of polyamides [603–605]. Other polymers obtained from cyclic carbonates increase the impact and fracture resistance of poly(alkylene terephthalates) [606]. The addition of bicyclic carbonates results in polymerization with cross-linking to yield hard, elastic, and impactresistant thermosets with very good glass adhesion [437], [607], [608]. Polymers with OH end groups made from neopentyl glycol carbonate are suitable for the manufacture of PU rubber [609]. Cyclic carbonates produced from derivatives of trimethylpropane offer further options for the manufacture of new homopolymers and copolymers [610], [611]. The copolymers with allylic double bonds can be radically cross-linked [612]. Furthermore, copolymers have been produced with aromatic cyclic carbonates, acrylates, styrene, polyethers, and siloxanes, the potential applications of which are by no means exhausted [613–615].

An interesting new field of application for polymers and copolymers made from six-membered cyclic carbonates, lactones, lactide and glycolide is in medicine as these polymers are biocompatible, biodegradable and resorbable. They are thus suitable for drug-release implants, sutures, and tissue and repair materials [616–619]. Polymers made from cyclic carbonates are recyclable and are easily cleaved into monomers by thermal degradation [620], [621].

Cyclic aliphatic carbonates, especially that based on trimethylolpropane, are now used in the manufacture of high-quality polyurethane coatings [622–625].

EC can also be polymerized [626]. However, the reaction of EO with CO_2, which yields polymers directly [627], [628], is more important. These have a good barrier effect to oxygen and moisture and are suitable for the manufacture of packaging films [629–631].

9. Economic Aspects [117–119], [120], [252], [632–653]

Large amounts of carbonates do not reach the market as they are used primarily as intermediates. However, this could change if DMC with an oxygen content of 53 % were used to increase the octane number of gasoline or to purify diesel exhaust. Today, DMC and DPC are the most important carbonates in terms of volume. DMC is produced by ENI (ca. 12 000 t/a; oxidative carbonylation) for a number of products, General Electric in Spain (ca. 60 000 t/a) and General Electric Plastics in Japan (ca. 18 000 t/a; both using the ENI process), SNPE in France (ca. 1000 t/a; via phosgene), in Tongling, China (1000 t/a; PC/MeOH transesterification), Ube (12 000 t/a; oxidative carbonylation with NO_x, with planned expansion to 50 000 t/a), Nanjing Chem. Ind. in China (600 t/a), Hoechst Celanese, PPG, Mitsubishi, and BASF.

General Electric has purchased a license from ENI for the DMC and DPC processes and is working with these in two Bisphenol A polycarbonate plants operating the melt process (130 000 t/a in Spain, 45 000 t/a in Japan with plans to expand to 260 000 t/a in Spain). This is equivalent to a total DPC volume of ca. 280 000 t/a. Other DPC manufacturers are Bayer, BASF, ENI, SNPE, PPG, Mitecs, and Mitsubishi.

In addition to Bisphenol A polycarbonate, DPC is also used in the synthesis of methyl isocyanate (crop protection products) and 1,6-hexanediol polycarbonate. DMC can also be used to produce aliphatic polycarbonates, lubricants, methylated phenols, crop protection products, pharmaceuticals and isophorone diisocyanate, as is intended by a joint venture between Daicel and Degussa-Hüls AG.

EC and PC are used as solvents and extractants but also in other reactions, e.g., in DMC synthesis in Nanjing and Tongling. Dow, Degussa-Hüls, BASF, Arco, and Texaco also produce cyclic carbonates, and Ube produces glycerin carbonate.

DEC, primarily used as a solvent, is manufactured by SNPE, BASF, Bayer, Mitsubishi, Wuxian (China), and Essex Chem. (USA).

The kilogram price of the carbonates available in large quantities is around $ 1 – 3. Special carbonic esters can command higher prices.

The economic significance of carbonic esters will continue to increase since they are intermediates with a wide range of uses, are easy to handle, and satisfy the growing demand for environmentally friendly processes and high-quality products.

1. Introduction

Carbon monoxide [*630-08-0*], CO, is a toxic gas generated by the incomplete combustion of carbon-containing compounds. It was first prepared and isolated in 1776 by J. M. F. DE LASSONE by heating a mixture of zinc oxide and charcoal. However, its chemical composition was only recognized 20 years later by W. CRUIKSHANK and confirmed by F. CLEMENT and J. B. DESORMES (1801).

Considerable amounts of carbon monoxide enter the atmosphere from natural processes. According to research done in the 1970s less than 10 % comes from man-made emissions and 80 % of the estimated 3.8×10^9 t originates from oxidation of methane emitted by decaying organic matter [1]. Recent research estimates the emission from the combustion of fossil fuels at 600×10^6 t and the total emission at 2.5×10^9 t [2]. Substantial concentrations of CO can be detected in the air of major urban areas, primarily due to emissions from vehicle exhausts and domestic heating. Environmental regulations and concerns are strong incentives to reduce the amount of CO released to the atmosphere.

Carbon monoxide can also be found in abundance in the atmosphere of other planets of our solar system and in interstellar space [3], [4].

Industrial production of CO is based mainly on coal gasification or steam reforming of natural gas or petrochemicals. Major applications are as a reducing agent for the production of metals, in the production of hydrogen by the water-gas shift reaction, and for the carbonylation of organic substrates such as alcohols, amines, and esters.

Mixtures of hydrogen and carbon monoxide (syngas) are used as feedstocks of growing importance for the large-scale production of several chemicals such as methanol [*67-56-1*] and aliphatic alcohols and aldehydes (oxo synthesis). Market studies show that demand for this application will increase dramatically up to 2010 [5].

2. Physical Properties

Carbon monoxide, CO, is a colorless, odorless, tasteless, and highly flammable gas at room temperature and atmospheric pressure. In the solid state, two different allotropic phases are

known at low temperature. Cubic α-CO exists below 61.55 K, and hexagonal β-CO above that temperature. The melting point of solid carbon monoxide is 68.15 K (at 15.35 kPa) and increases with pressure according to the following equation [6]:

$$T = 68.146 + 2.229 \times 10^{-7} p - 2.55 \times 10^{-16} p^2$$
$$\text{overtherange } p = 0.1 - 25\text{MPa}.$$

Table 2. Physical properties of carbon monoxide

Molecular mass M_r	28.011
Critical temperature	132.91 K
Critical pressure	3.4987 MPa
Boiling point (at 101.3 kPa)	81.63 K
Triple point temperature (at 15.35 kPa)	68.15 K
Phase transition point (at 3.75 kPa)	61.55 K
Density of gas (STP)	1.250 kg/m^3
Density at critical point	301.0 kg/m^3
Density of liquid (at 81.63 K)	788.6 kg/m^3
Density of solid, hexagonal (at 65 K)	929.0 kg/m^3
Density of solid, cubic (at 20 K)	1028.8 kg/m^3
Heat capacity of gas (298 K, 101.33 kPa)	
c_p	29.142 J mol^{-1} K^{-1}
c_v	20.769 J mol^{-1} K^{-1}
Heat capacity of liquid (76 K)	60.351 J mol^{-1} K^{-1}
Heat of vaporization (at 81.63 K)	6.042 kJ/mol
Heat of fusion at triple point	837.3 J/mol
Heat of sublimation at triple point	7.366 kJ/mol
Heat of transition	632.11 J/mol
Free energy of formation of gas (at 298 K), ΔG_f^0	− 137.381 kJ/mol
Enthalpy of formation of gas, ΔH_f^0	− 110.63 kJ/mol
Entropy of gas (at 298 K, 101.33 kPa), S^0	197.89 J mol^{-1} K^{-1}
Viscosity of gas (at 273 K)	16.62 μN s/m^2
Refractive index of gas (at 273 K, 546.1 nm)	1.0003364
Surface tension of liquid (at 80 K)	9.8 mN/m
Thermal conductivity of gas (STP)	23.15 mW m^{-1} K^{-1}
Thermal conductivity of liquid (at 80 K)	0.1428 W m^{-1} K^{-1}
Dielectric constant of gas (at 298 K, 101.33 kPa)	1.000634
Electric conductivity of liquid (at 85 K)	9.43 × 10^{-19} S/m
Autoignition temperature	ca. 880 K
Flammability range in air	12.5 – 74.2 vol %
Flammability range in oxygen	15.5 – 93.9 vol %

The boiling point at atmospheric pressure is 81.63 K and the vapor pressure (in MPa) of liquid CO can be calculated by using the following equation [7]:

$$\log_{10} p = A/T - B \log_{10} T + CT + D$$

where $A = 612.904$, $B = 12.968013$, $C = 0.02709872$, and $D = 29.09142$ over the range $T = 90 - 130$ K.

Selected values are given in Table 1. Other physical and thermodynamic values are presented in Table 2 [8–12]. Carbon monoxide is sparingly soluble in water and in organic solvents (Table 3) [13–15].

Table 3. Solubility of carbon monoxide in various solvents

3. Chemical Properties

Carbon monoxide is an unsaturated molecule. Its chemistry is dominated by its reducing properties and its ability to combine with a large variety of molecules.

3.1. Molecular Structure of Carbon Monoxide

Carbon monoxide is isoelectronic with N_2 and the predicted electronic configuration of the valence shell is:

$$\left(\sigma_{\mathrm{s}}^{\mathrm{b}}\right)^2 (\sigma_{\mathrm{s}}^{*})^2 \left(\pi_{\mathrm{x,y}}^{\mathrm{b}}\right)^4 \left(\sigma_{\mathrm{z}}^{\mathrm{b}}\right)^2$$

The energy levels of the molecular orbitals are shown in Figure 1. There are three bonds between the carbon and oxygen atoms: one sigma bond and two pi bonds. A very short C – O bond length 112.82 pm, a large bond dissociation energy 1.070 MJ/mol [16], and a high infrared stretching frequency $\tilde{\nu}_{\mathrm{CO}} = 2143.274\,\mathrm{cm}^{-1}$ (gas), $\tilde{\nu}_{\mathrm{CO}} = 2138.44\,\mathrm{cm}^{-1}$ (solid, 20 K) [17] are consistent with a carbon – oxygen triple bond. The first ionization potential is 1.351 MJ/mol (14 eV).

Figure 1. Simple molecular orbital diagram for CO [16]

3.2. Coordination with Transition Metals

Carbon monoxide is an extraordinarily widely used ligand (carbonyl) of utmost importance in coordination chemistry [18]. Synergic bonding occurs due to the slight donor character of the σ_z bonding orbital (σ donation from the carbonyl to an empty orbital of the metal having the correct symmetry) and the presence of two empty low-lying $\pi_{x,\,y}*$ antibonding orbitals which may act as strong π acceptors (π back donation from a filled π orbital of the metal), as depicted in Figure 2. The net effect is an electron density transfer from the σ_z bonding orbital to the $\pi_{x,\,y}*$ antibonding orbitals of the carbonyl ligand that results in an increase of the C–O bond length and a lowering of the infrared carbonyl stretching frequency compared with that of free carbon monoxide. Moreover, the stabilization of the $\pi_{x,\,y}*$ antibonding orbitals of the carbonyl ligand and prepare it for nucleophilic attack; this is an essential step in the activation of carbon monoxide by transition metals. Coordination can occur on a single metal center (monodentate carbonyl) with a linear or quasilinear M – C – O geometry (**1**) (Fig. 3). Numerous complexes having bridging (**2**) or capping carbonyl ligands(**3**) have been described and play a very important role in polymetallic cluster chemistry [19–21], as well as in the chemisorption of carbon monoxide on surfaces [22]. Carbonyl ligands have also been used extensively as internal probes for electronic effects in transition-metal complexes because their infrared stretching frequencies are highly sensitive to the charge density on the metal [23].

Figure 2. Synergic binding of CO to transition metals Arrows indicate the electron donation from filled (hatched) to empty orbitals

Figure 3. Some common geometries of CO coordination with transition metals

3.3. Chemical Reactivity

Carbon monoxide is a metastable molecule. It is almost inert under mild conditions, but it be-

comes very reactive when subjected to high pressure or elevated temperature, and it can be easily activated by catalysts. Carbon monoxide disproportionates to form carbon and carbon dioxide (Boudouard equilibrium).

$$2\,CO \rightleftharpoons CO_2 + C$$

$$\Delta H^0_{298} = -172.47\,\text{kJ/mol};\ \Delta G^0_{298} = -120.02\,\text{kJ/mol}$$

At atmospheric pressure, the extent of carbon monoxide disproportionation is very low below about 670 K, the temperature at which the thermodynamic equilibrium is almost completely displaced toward carbon and carbon dioxide, whereas less than 1 % of carbon dioxide is observed at equilibrium above 1250 K.

This disproportionation reaction, which is favored by increased pressure, is catalyzed by a large number of metals or metal oxides and is responsible for the undesirable formation of carbon deposits in places such as blast furnaces.

Carbon monoxide is extremely flammable. It has a large flammability range (see Table 2) and can form explosive mixtures in air. Carbon monoxide burns with a blue flame.

$$CO + 0.5\,O_2 \rightarrow CO_2$$

$$\Delta H^0_{298} = -282.98\,\text{kJ/mol};\ \Delta G^0_{298} = -257.19\,\text{kJ/mol}$$

It may also react violently with oxidants. Hopcalite, a mixture of the oxides of manganese, copper, cobalt, and silver, has been used in gas-mask elements to oxidize carbon monoxide. Also important are ceramic-supported transition metals of Groups 8 – 10, especially palladium, platinum, and rhodium, which are used as catalytic converters to reduce carbon monoxide emissions in vehicle exhaust [24].

The carbon monoxide reactions of greatest industrial importance are described in Chapter 9.

4. Production

Carbon monoxide is formed by the incomplete combustion of carbonaceous materials or by the reduction of carbon dioxide [25], [26]. It can also be formed by the decomposition of organic compounds such as aldehydes [27]. Carbon monoxide can also be recovered from the off-gas of several industrial processes such as blast furnace processes or calcium carbide synthesis.

4.1. Laboratory-Scale Production

Although readily commercially available in high purity, carbon monoxide can be prepared by the slow addition of concentrated formic acid (90 %, $d = 1.2$) to concentrated sulfuric acid at about 350 K [28], [29]. Traces of sulfur dioxide and carbon dioxide can be removed by passing the gas through a column filled with potassium hydroxide pellets.

4.2. Industrial Production

Incomplete combustion of carbonaceous materials is commonly employed for the manufacture of commercial quantities of carbon monoxide. The only process that can produce carbon monoxide with a very low content of hydrogen and nitrogen is the Otto process, which is an interesting possibility for smaller plants [30]. In most production processes the initial product is a gas mixture containing carbon monoxide. The most important processes are:

1) Gasification of coal
2) Steam reforming/CO_2 reforming (for light hydrocarbons up to naphtha)
3) Partial oxidation of hydrocarbons (for hydrocarbons heavier than naphtha)

To obtain the pure gases, the mixtures must be separated. The main gas that is produced together with carbon monoxide is hydrogen. Many applications need a synthesis gas that is a combination of carbon monoxide with hydrogen. Therefore the separation of carbon monoxide or the adjustment of the carbon monoxide hydrogen ratio are the following production steps. The CO can be separated by various procedures:

1) Reversible complexation (copper ammonium salt wash) at elevated pressure, followed by desorption by pressure release
2) Cryogenic separation
   Low-temperature partial condensation and fractionation
   Liquid methane scrubbing and separation
3) Pressure-swing adsorption
4) Permeable membranes

4.2.1. Gasification of Coal

Coal gasification is the term for several methods for the conversion of coal into gaseous reaction products in generators of different construction.

Coal is gasified at an elevated temperature when reacted with steam and air or preferably oxygen [31–39]. The main reaction is the endothermic water – gas reaction:

$$C + H_2O \rightleftharpoons CO + H_2 \quad \Delta H^0_{298} = +131.30\,\text{kJ/mol}$$

This is coupled with exothermic carbon combustion:

$$C + O_2 \rightleftharpoons CO_2 \quad \Delta H^0_{298} = -394.36\,\text{kJ/mol}$$

Several other reactions are involved in the process. Among these are the previously mentioned Boudouard equilibrium and the subsequent water-gas shift reaction.

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad \Delta H^0_{298} = -41.16\,\text{kJ/mol}$$

The composition of the raw gas is highly dependent on the C : H_2O : O_2 ratio, the temperature, and the nature of the coal feedstock.

Three types of coal gasifiers, using either fixed-bed, fluidized-bed, or entrained-bed technology, have been operated commercially for many years (Table 4). A Texaco unit (entrained-bed, operating pressure of up to 8 MPa) started operating in 1983 consuming coal at a rate of 900 t/d. Several new gasifiers have been developed by various companies, including Shell and Dow Chemical [40–48]. The feasibility of the gasification of low-grade fossil fuels such as shale oil and tar sands has also been investigated [49].

4.2.2. Steam Reforming

Carbon monoxide can also be produced by steam treatment of natural gas or light petroleum fractions (naphtha) [50–52].

$$CH_4 + H_2O \rightleftharpoons CO + 3\,H_2 \quad \Delta H^0_{298} = +206.15\,\text{kJ/mol}$$

$$\text{or } C_n H_2{}^{n+2} + n\,H_2O \rightleftharpoons n\,CO + (2n+1)\,H_2$$

These highly endothermic reactions are usually carried out at 1000 – 1100 K with external heating, under a pressure of 1.5 – 4 MPa in the presence of a catalyst. The catalyst is nickel promoted with K_2O, deposited on a refractory support (e.g., ICI process). Sulfur-free feedstocks (less than 0.2 mg/kg) are required to avoid poisoning of the catalyst.

The reaction of a hydrocarbon with carbon dioxide is analogous to steam reforming with water vapor. Therefore, it is often called CO_2 reforming. The reformer fuel, for example LPG, together with carbon dioxide is exposed to a high temperature in the presence of a catalyst and is thereby transformed by an endothermic reaction into a mixture of carbon dioxide, water, hydrogen and carbon monoxide. The carbon dioxide removed from the raw synthesis gas at the outlet of the reformer can be recycled for the reforming process; thus, an H_2/CO ratio of 3/1 can be achieved. By adding imported CO_2 a further decrease of the H_2/CO ratio is possible. In practice the lower limit is 1.2 [53].

4.2.3. Partial Oxidation of Hydrocarbons

Hydrocarbons, e.g., methane, can be partially oxidized by using a limited amount of oxygen.

$$CH_4 + 1.5\,O_2 \rightleftharpoons CO + 2\,H_2O \quad \Delta H^0_{298} = -519.33\,\text{kJ/mol}$$

Such reactions are performed at 1500 – 1800 K and 3 – 8 MPa without a catalyst.

Several processes have been designed (BASF-Lurgi, Texaco, Hydrocarbon Research, Shell, etc.) to use petroleum feedstocks ranging from natural gas to asphalt [54].

4.3. Separation of Carbon Monoxide from Gas Mixtures

The previously mentioned preparations and the recovery of CO from various industrial processes (blast furnace processes, acetylene synthesis, etc.) yield gas mixtures containing 30 – 85 % of carbon monoxide. Usually a preliminary purification step is performed to remove acidic contaminants (CO_2, COS, H_2S, mercaptides) by using one of the numerous basic washing processes [55]. Pure carbon monoxide is obtained either by reversible complexation or cryogenic separation.

Table 4. Characteristics of commercially operated gasifiers

Parameter	Gasification process		
	Lurgi (fixed- bed)	Winckler (fluidized- bed)	Koppers- Totzek (entrained-bed)
Feed size, mm	6 – 40	1	< 0.1

∗ Dependent on the nature of the feed.

4.3.1. Separation by Reversible Complexation

Copper(I) salt solutions are able to absorb carbon monoxide to form carbonyl complexes [56]. This property is used in two industrial processes to selectively separate carbon monoxide from a mixture of gases. The copper – ammonium salt wash developed by BASF uses aqueous ammonia solutions of copper carbonate, formate, acetate, lactate, or a mixture thereof [57]. The absorption – desorption reaction is thought to be an equilibrium between free and coordinated carbon monoxide that is highly dependent on the temperature, pressure, and acidity of the medium.

$$[Cu(NH_3)_2]^+ + CO + NH_3(aq) \rightleftharpoons [Cu(NH_3)_3(CO)]^+$$

The solution composition is adjusted to ensure maximum solubility of copper(I) and thereby increase the productivity (volume of carbon monoxide absorbed per unit volume of solution).

A simplified flow diagram of the copper – ammonium salt wash process is shown in Figure 4.

The gas containing carbon monoxide is contacted with the copper – ammonium salt solution in countercurrent at 283 – 303 K and a pressure of up to 20 MPa in a tower packed with Raschig rings. Carbon monoxide, which can be extracted down to a few mg/kg, is recovered in the regenerator by heating the rich solution to 350 K, usually at atmospheric pressure. The vapor pressure of ammonia at this temperature is significant and a scrubber can be used to wash the off-gas.

Figure 4. Simplified flow diagram of the copper – ammonium salt wash process
a) Absorption tower; b) Regenerator; c) Heaters; d) Ammonia scrubber; e) Cooler; f) Lean-solution recycle pump

The Cosorb process, developed in the early 1970s by Tenneco Chemicals, is based on a similar principle (Fig. 5) [58–60]. However, the use of copper(I) organometallic complexes in organic solvents (preferably $CuAlCl_4$ in toluene) as carbon monoxide carriers provides several advantages such as lower corrosion, higher complex stability, and higher purity of the gas produced. Nevertheless, several impurities such as water or sulfur compounds (SO_2, H_2S, COS, etc.) destroy the copper complex. A very careful purification of the feed gas is therefore required.

The mixture of gases is washed with a countercurrent flow of the copper complex solution in the absorber (on a packed column or in trays) at a moderate temperature of 303 – 318 K and a pressure of 0.7 – 3 MPa. The rich solution is then

decompressed to release physically dissolved gases, e.g., H_2, N_2, which can be either recycled in the absorber or eliminated. The carbon monoxide is stripped in the regenerator by lowering the pressure to ca. 0.15 MPa and heating the solution to 408 K. Solvent losses in the absorber and regenerator overhead gas flows are minimized by using a combination of compression, refrigeration, and activated charcoal recovery. Carbon monoxide can be obtained with a purity up to 99.7 % and yield of 95 – 99 %.

Figure 5. Simplified flow diagram for the Cosorb process

Some new CO-complexing compounds and liquid absorption processes are under investigation [61].

4.3.2. Cryogenic Separation

Processes for the cryogenic separation of pure carbon monoxide from a mixture of gases have been developed by, among others, l'Air Liquide [62] and Linde [63]. The feed gas must be carefully purified to eliminate any traces of contaminants such as water and carbon dioxide that would freeze in the unit and thus cause clogging problems. This is usually achieved by pretreatment with molecular sieves. Carbon monoxide and nitrogen are difficult to separate by distillation, and feed gases containing nitrogen are therefore not suitable for production of high-purity carbon monoxide unless a nitrogen – carbon monoxide separation device is included in the process.

The *low-temperature partial-condensation process* (Fig. 6) utilizes the difference in boiling points between carbon monoxide and hydrogen. The purified mixture of gases is cooled to approximately 80 K at 3 – 4 MPa by means of heat exchange with the exhaust gases. Carbon monoxide and methane, which may possibly be present in the feed, condense and are recovered as liquid in the first separator. In the second separator, which is operated at a lower pressure, dissolved hydrogen is released, recovered overhead, and recycled to the feed gas after recompression. The liquid phase, rich in carbon monoxide, is evaporated in the heat exchanger to yield gaseous carbon monoxide of 98 – 99 % purity ($CO + N_2 > 99.5$ %). If the feed contains too much methane for the required purity, it is possible to introduce a carbon monoxide – methane separation column after the second separator to obtain a final concentration of methane as low as 0.1 % in the product gas.

Figure 6. Simplified flow diagram for the partial condensation process for obtaining carbon monoxide and hydrogen
a) Heat exchanger; b) Liquid – gas separator; c) Hydrogen expansion turbine; d) Recycle compressor

The hydrogen-enriched phase collected overhead from the first separator is further cooled to ca. 70 K to condense more carbon monoxide. At this stage the gas phase contains 96 – 98 % pure hydrogen, which is passed through the heat ex-

changer to cool the incoming flow of impure hydrogen. The necessary refrigeration is provided by the decompression of a part of the hydrogen in an expansion turbine and the vaporization of the carbon monoxide rich liquid phase coming out of the third separator. The cryogenic part, usually referred to as the cold box, includes heat exchangers, phase separators, and, in some cases, fractionating columns. Perlite or rock wool is used to ensure efficient thermal insulation.

Figure 7. Simplified flow diagram for the methane wash process for obtaining carbon monoxide and hydrogen
a) Heat exchanger; b) Methane absorption tower; c) Heat exchanger; d) Regenerator; e) Carbon monoxide recycle compressor; f) Hydrogen expansion turbine

The *liquid methane wash process* (Fig. 7) takes advantage of the considerable solubility of carbon monoxide in cooled liquid methane. The feed gas at a pressure of about 4 MPa is cooled to 92 K in a heat exchanger to condense most of the carbon monoxide and methane. The gas phase, after countercurrent scrubbing with liquid methane to extract carbon monoxide (to a few mg/kg), is collected overhead and decompressed to ca. 1.5 MPa in an expansion turbine. This provides the refrigeration for the incoming gas flow, which contains 97 – 99 % pure hydrogen contaminated with small amounts of methane (1 – 1.5 %). The condensed phase from the scrubber is fed after partial decompression to a carbon monoxide – methane separation column operating at 0.1 – 0.2 MPa. Liquid methane is recovered at the bottom of the column and recompressed. Part of it is vented as a low-pressure fuel to ensure the cooling of the primary heat exchanger. The main stream is recycled through the top of the scrubber. Carbon monoxide is recovered overhead from the separation column with an excellent yield of 97 – 99 % and circulated to provide cryogenic power for the unit. Its purity is about 97 – 99 % ($CO + N_2 > 99.8$ %). Hydrogen is the main impurity along with a small amount of methane.

4.3.3. Pressure Swing Adsorption and Membrane Separation

Pressure swing adsorption (PSA) and membrane separation are used for lower production capacities if CO purities up to 99 % are required. The attainable CO content depends very much on the raw gas composition and is affected by the presence of nitrogen. Both processes are more suitable for recovery of pure hydrogen than for CO. Pressure swing adsorption is used today almost exclusively in new steam reforming hydrogen plants.

Molecular sieve adsorbents for the removal of specific components from a gas mixture are selected on the basis of their relative adsorptive power. The PSA process uses multiple adsorbent beds to provide continuous flow under constant-pressure conditions. Molecular sieves adsorb preferentially carbon monoxide, carbon dioxide, methane, and nitrogen from the raw synthesis gas. Other CO-selective adsorbents have been investigated [61]. In the PSA process the absorber swings between high pressure for absorption and low pressure for desorption.

An excellent solution for the simultaneous production of carbon monoxide and hydrogen is a combination of cryogenic partial condensation followed by a PSA unit [64].

Two commercial PSA plants have been in operation in Japan since 1989 for the recovery of CO from converter gases of steel plants [65].

Depending on the use of the syngas the desired composition ranges from 100 % hydrogen (for the production of hydrogen or ammonia) to 100 % CO for carbon monoxide or acetic acid production.

The first application of membrane processes in syngas separation was the adjustment of carbon monoxide to hydrogen ratio. Monsanto has developed a partial separation process that uses silicon-coated polysulfone hollow-fiber gas permeators (trade name: PRISM) [66–72]. Each gas permeator consists of an array of 10 000 – 100 000 hollow fibers embedded in a permeable and nonselective matrix. Hydrogen diffuses faster, permeates the fibers, and is re-

covered at low pressure, whereas the adjusted $CO-H_2$ mixture is obtained as the high-pressure residual gas (Fig. 8).

Figure 8. Principle of hollow-fiber gas separators (each contains 10 000 – 100 000 hollow fibers)
Data are taken from ref. [67]

For production of pure CO from natural gas reformed syngas a two-stage membrane system has been demonstrated to yield 98.9 % purity.

For both syngas ratio adjustment and CO production cellulose acetate was found to provide higher selectivity and permeability compared to a polysulfone membrane under the same operating conditions.

5. Environmental Protection

The concentration of CO in the atmosphere in the northern hemisphere is currently about 140 ppb ($\mu L/m^3$), compared to a pre-industrial concentration of 90 ppb [2]. Model calculations predict an approximate doubling of the CO concentration by 2100 [73].

According to research done in the 1970s, 3.0×10^9 t of the 3.77×10^9 t in the atmosphere originate from oxidation of methane emitted by decaying organic matter and only 270×10^6 t from man-made emissions [1]. Traces of CO are emitted during composting of grass and green waste. Quantitative measurements have been performed [74]. Recent estimates of the emission from the combustion of fossil fuels are around 600×10^6 t [2].

The lifetime of the CO molecule in the atmosphere is currently (2000) two months and is estimated to increase to 2.6 months by 2100 [73]. The lifetime-limiting reaction in the troposphere is [75]:

$$CO + OH \longrightarrow CO_2 + H$$

An increase in CO concentration is likely to cause a decrease in OH and O_3 in the troposphere, and this would result in extensive chemical feedback. The global budget and trends of CO are therefore of considerable environmental importance.

Air pollution by carbon monoxide is restricted almost entirely to urban and highly industrialized areas. CO plays an important role in photochemistry of regional and urban environments where, depending on the concentration of nitrogen oxides and hydrocarbons, CO can produce ozone, which is implicated in photochemical smog and haze.

During the past years all leading industrialized countries have significantly intensified their efforts to lower air pollution. (e.g., Clean Air Act amendments of 1970, 1977 and 1990 in the USA, TA Luft in Germany). One of the consequences is the substantially improved exhaust gas purification for vehicles by catalytic converters. By 1995 over 85 % of all new gasoline-powered cars sold worldwide had either a three-way or oxidation-only catalytic converter [76]. Today in urban main roads CO levels of about 5 ppm can be observed. Inside the motor vehicle the mean level of CO is about 20 ppm [77].

In addition, households and small-scale fuel consumers switched to liquid and gaseous fuels with considerably better emission values, and for industrial combustion units improved burner designs were developed.

The success of emission control in the industrial countries is exemplified for Germany and the United States. In Germany carbon monoxide emissions increased until the beginning of the 1970s. Since then a continual decrease was observed. From 1990 to 1994 the emission of CO decreased from 10.743×10^6 t/a to 6.738×10^6 t/a. The contribution of traffic decreased slightly from 60.4 % to 58.7 %. But despite the fall in absolute emissions, traffic remains the most significant cause of CO pollution.

In the USA nationwide emissions of CO from on-road vehicles fell by 33.4 % from 1970 to 1995. Since 1981 each car sold outside the state of California emitted only 2.1 g/km. Prior to 1968 each new passenger car emitted 48 g/km [76].

According to the EC Exhaust Emission Directive 94/12/EC (phase 2) the emission for gasoline engines is set at 2.2 g/km (new type approval from 1.1.96) From January 2005 (phase 4) the emission will be limited to 1.0 g/km

[78]. Based on the EC guidelines for the reduction of emissions of motor vehicles, the German Umweltbundesamt (Federal Department for the Environment) has calculated a reduction in CO emissions of 56 % between 1988 and 2005.

6. Quality Specifications

Carbon monoxide of high purity is available in cylinders as the compressed gas (10 – 20 MPa) in volumes of 0.1 – 9.5 m^3 (STP). No standard specifications have been issued by the Compressed Gas Association, and each supplier uses its own quality label. Carbon monoxide is sold in different purities [79–82]:

Commercial (technical, standard) grade 98 – 99 %
C. P. grade 99.3 – 99.5 %
Ultrahigh-purity grade 99.8 %
Research grade 99.99 – 99.997 %

Contaminants include primarily nitrogen, hydrogen, methane, oxygen, water, carbon dioxide, and argon. Carbonyls are normally not specified. If iron or nickel carbonyls are of special concern, aluminum cylinders and brass valves are better suited than carbon steel cylinders with stainless steel valves.

7. Analysis

Environmental pollution control has been an incentive to develop fast and reliable methods for the determination of traces of carbon monoxide. Nondispersive infrared spectrometry takes advantage of the strong absorption of CO at 4.7 µm. The lower limit of detection is about 0.5 mg/kg. Water vapor and, to a lesser extent, CO_2 interfere [83]. Semicontinuous measurement of carbon monoxide can be carried out by using gas chromatography with different detectors, depending on the required detection limit [84]. A reduction gas detector (RGD) is especially suited for the detection of traces of CO. It is specific to gases that can reduce a bed of mercury oxide. The released mercury can be detected by ultraviolet absorption at ppb levels (DIN 50450-7, 1995). Another common detection method uses the conversion of carbon monoxide into methane with a catalyst (DIN 50450-6, 1994). An absolute method, which is independent of calibration gases, is complete oxidation with I_2O_5 and titration of the elemental iodine (VDI 2459, Blatt 7, 1994). A turbidimetric method can determine 2 – 1800 mg/kg CO [85] by reducing a solution of a silver salt of *p*-sulfaminobenzoic acid to a colloidal silver derivative; absorbance is measured at 425 or 600 nm. No interferences are known for this method. Other analytical techniques include catalytically oxidizing carbon monoxide to carbon dioxide by using Hopcalite, platinum-group metals, or miscellaneous catalysts and monitoring the heat of reaction. The colorimetric tubes in some portable analyzers use the wet oxidation with I_2O_5, whereby a reactive adsorbent turns greenish brown as it adsorbs the iodine formed. Semiquantitative analysis can be performed by using a solution of palladium chloride, which is reduced by carbon monoxide to a black precipitate of metallic palladium.

8. Storage and Transportation

The standard quality of carbon monoxide has considerably improved during the last decades, especially in regard to moisture and sulfur-containing impurities. Dry, sulfur-free carbon monoxide is satisfactorily compatible with steel and other commonly used metals at pressures up to 15 MPa or even 20 MPa (these filling pressures are used for commercially available carbon monoxide in gas cylinders). Moisture and sulfur-containing impurities in carbon monoxide increase the corrosion of steel at all temperatures. Only highly alloyed chrome steels are sufficiently resistant to corrosion by CO containing these impurities. Iron, nickel and other metals can react even at room temperature with carbon monoxide at elevated pressures to form carbonyls in small quantities. Copper and copper – silver alloys are the only materials suitable for applications at high temperature and pressure. Carbon monoxide is also compatible with synthetic organic materials such as polyethylene, poly(vinyl chloride), Kel F, Teflon, and Viton. However, the use of rubber or Neoprene is forbidden.

Carbon monoxide is produced or recovered almost exclusively for on-site uses. Although available in the United States in bulk quantities

as a liquified gas, it is much more commonly transported as a compressed gas in tube trailers or cylinders (steel or, more frequently, aluminum or its alloys). In most countries, the cylinders must be recertified every five years.

There is no color international standardization for the marking of cylinders. In the European community there is a new standard (EN 1089-3) for the color marking of cylinders. Carbon monoxide container heads are painted with yellow, or yellow and red. The color of the cylindrical part is generally not specified. In Germany the gas industry agreed to use gray or the new or the old color of the shoulder. For CO this means that the cylindrical part is painted in gray or red.

Transportation of carbon monoxide is subject to a number of regulations [86–89]. According to transport regulations in Europe the containers must bear labels for flammable and toxic substances (with a skull and cross-bones). Since October 1999 in the US the DOT requires the labels "Flammable Gas" and "Inhalation Hazard" (with the poison symbol).

9. Uses

Carbon monoxide, as a pure compound or as a constituent of syngas ($CO + H_2$), is increasingly being used on a very large scale for the production of chemical intermediates.

9.1. Production of Inorganic Chemicals

As a component in the raw gas mixture after gasification carbon monoxide is used in the production of hydrogen in the water-gas shift reaction (→ Hydrogen, Chap. 4.1.).

Carbon monoxide is one of the reducing agents acting on oxides in blast furnaces. Direct reduction of iron ore to sponge iron by using syngas as an alternative technology has made rapid progress [90]. Some transition metals react under pressure with carbon monoxide to yield metal carbonyls such as $[Ni(CO)_4]$, $[Fe(CO)_5]$, $[M(CO)_6]$, (where M = Cr, Mo, or W), $[Co_2(CO)_8]$, etc. These are used as precursors for making homogeneous catalysts or for the preparation of very pure metals; e.g., the extractive metallurgy of nickel uses $[Ni(CO)_4]$ as an intermediate in the carbonyl refining processes (→ Nickel, Chap. 6.3.).

The reaction of carbon monoxide with chlorine, catalyzed by activated charcoal, yields phosgene, an intermediate in the synthesis of isocyanates.

$$CO + Cl_2 \rightarrow COCl_2$$

Phosgene or a mixture of carbon monoxide and chlorine is used to prepare aluminum chloride by the chlorination of bauxite [91].

9.2. Production of Organic Chemicals

Carbon monoxide is widely used in the production of organic chemicals [92–105].

From Pure Carbon Monoxide. The major use of pure carbon monoxide is in the preparation of acetic acid [*64-19-7*] by catalytic carbonylation of methanol [*67-56-1*]. This consumes more than 500 000 t/a.

$$CH_3OH + CO \rightarrow CH_3COOH$$

Cobalt promoted with iodides is used as the catalyst in the BASF process (470 – 520 K, up to 70 MPa, 90 % selectivity based on CH_3OH). The rhodium-based Monsanto process requires much less severe conditions (440 – 450 K, 1 – 4 MPa, 99 % selectivity) [106]. Processes using cheaper catalysts such as nickel (Rhône-Poulenc, Mitsubishi-Gas, Halcon) have been tested at the pilot-plant stage. Analogously, a plant that uses the carbonylation of methyl acetate [*79-20-9*] (Eastman Kodak-Halcon) is producing acetic anhydride [*108-24-7*] at the rate of 250 kt/a [107]. Other uses of pure carbon monoxide include the production of formic acid [*64-18-6*] and methyl formate [*107-31-3*] in the presence of a basic catalyst (350 – 420 K, 1 – 20 MPa).

$$CO + ROH \rightarrow HCOOR \quad R = H, CH_3$$

N,N-Dimethylformamide [*68-12-2*] is prepared from dimethylamine [*124-40-3*] under similar conditions.

$$CO + HN(CH_3)_2 \longrightarrow HCON(CH_3)_2$$

Acrylic acid [*79-10-7*] and propanoic acid [*79-09-4*] are also prepared by the hydroxy carbonylation (Reppe carbonylation) of acetylene [*74-86-2*] and ethylene [*74-85-1*], respectively, in the presence of a nickel catalyst (BASF).

$$HC \equiv CH + CO + H_2O \xrightarrow[4-5\ MPa]{450-470\ K} CH_2 = CH-COOH$$

and

$$CH_2 = CH_2 + CO + H_2O \xrightarrow[20-25\ MPa]{540-590\ K} CH_3-CH_2-COOH$$

From Syngas. A large variety of chemicals, ranging from saturated hydrocarbons to oxygenated compounds, are produced using syngas as a feedstock. The most important applications of syngas are in the production of

- Methanol (→ Methanol, Chap. 5.)
- Hydrocarbons (→ Coal Liquefaction, Chap. 2.2., → Waxes, Chap. 5.)
- Linear aliphatic aldehydes (→ Oxo Synthesis)

9.3. Application as a Merchant Gas

Most carbon monoxide is used on site directly after production. That which is sold as a merchant gas must be filled, transported, and for many applications also purified [108].

The demand for carbon monoxide as a merchant gas has grown strongly in the last few years. Applications include various test runs (e.g., turbines) with a high consumption for a limited time and smaller demands for industrial applications and research projects. Purities of up to 99.999 vol % are required for special purposes. In some cases, carbonyls must be removed by special purification techniques [109].

Uses for cylinder gases include:

- As a plasma etching gas in the electronic industry for selective oxide etching [109]
- As a component in calibration gas mixtures for environmental monitoring systems and for vehicle exhaust measuring systems
- In medicine as a component in gas mixtures for lung function tests
- As a component in CO_2 laser gas mixtures

10. Toxicology and Occupational Health

Carbon monoxide is a particularly dangerous chemical because it cannot be detected by the natural senses of the body [110], [111]. It is toxic because it competes successfully with oxygen for the binding sites of hemoglobin (Hb), the oxygen-carrying hemoprotein in the blood of mammals.

$$Hb + O_2 \rightleftharpoons HbO_2$$

$$Hb + CO \rightleftharpoons HbCO$$

The affinity of hemoglobin for carbon monoxide, calculated from the pressure of CO required for half-saturation, i.e., [Hb] = [HbCO], is 200 – 300 times higher than the affinity for oxygen [112]. The noxious effect of carbon monoxide is thus to deprive tissues of their required oxygen supply by hindering the oxygen-carrying activity of hemoglobin. Other hemoproteins can also be affected by carbon monoxide. Myoglobin, responsible for the storage of oxygen in muscles, is one example. Cytochrome P 450, the widespread monooxygenase involved in the metabolism of several essential biomolecules (e.g., steroids) and used for the detoxification of exogenous compounds by oxidative degradation, is another. At equilibrium the percentage of carboxyhemoglobin in blood can be estimated. The percentage of HbCO is 0.16 times the concentration of CO (expressed in mg/kg) [113]. However, equilibrium is reached slowly, requiring 5 – 10 h, depending on the physical activity of the subject. Low levels of carboxyhemoglobin are always present in the blood due to the endogenous production of carbon monoxide (ca. 0.45 mg/h) by the oxidative catabolism of heme proteins. Rarely are physiological effects observed if the proportion of carboxyhemoglobin is below 10 % (the HbCO level is frequently 4 – 5 % for smokers). The first toxic symptoms, a slight headache and shortness of breath, usually appear at about 20 % HbCO. Above 40 % HbCO, severe headache, weakness on exertion, dizziness, hearing and vision troubles, nausea, and eventual collapse are observed in conjunction with a cherry-red coloration of the skin. Unconsciousness and possibly death

can occur for a carboxyhemoglobin proportion of 60 – 70 %, and above 80 – 90 %, death occurs within minutes [114].

Carbon monoxide is not metabolized in the body, and the only mode of detoxification after poisoning is the displacement of carboxyhemoglobin with pure oxygen. The partial pressure of the oxygen is important for the effectiveness of detoxification; hyperbaric (2.0 to 2.5 bar) oxygen is advantageous. The Compressed Gas Association [86] still recommends the following procedure: If available, a mixture of oxygen with 7 – 10 vol % carbon dioxide will hasten the elimination of carbon monoxide from the bloodstream by acting as a powerful respiratory and cardiac stimulant, inducing deep breathing and rapid ventilation of the lungs. The victim will generally breathe more deeply with the administration of this mixture than with pure oxygen. Inhalation of this mixture should continue for at least 15 – 30 min. This constitutes the basis of emergency therapy. Severe carbon monoxide intoxication is generally believed to be harmless if limited to a brief period of time and if the appropriate treatment is quickly provided. However, chronic exposure to lower concentrations can result in irreversible brain damage and long-lasting heart trouble.

The TLV-TWA (ACGIH) is 25 mL/m^3 (29 mg/m^3) [115]. The exposure limit value for Germany is 30 mL/m^3, and the corresponding value for France is 50 mL/m^3.

The inhalation of concentrations of 400 mL/m^3 will result in headache and discomfort within 2 – 3 h. Inhalation of 4000 mL/m^3 concentration in air proves fatal in less than 1 h. Inhalation of high concentrations can cause sudden collapse with little or no warning [86] According to EC classification carbon monoxide may cause harm to the unborn child. CO is also on the California Proposition List 65 ("Carbon monoxide contains a chemical known to the State of California to cause birth defects or other reproductive harm.")

If carbon monoxide must be handled in a closed building, continuous monitoring of its concentration in the air with an automatic detection device is recommended [116]. Efficient ventilation is the simplest means of preventing carbon monoxide poisoning.

Carbonylation is a general method to produce carboxylic acid derivatives by homogeneous transition metal catalyzed reaction with CO. Today, more than 70 % of synthetic acetic acid production is based on rhodium- or iridium-catalyzed methanol carbonylation. Capacity of world-scale plants using this technology are in the range of 500×10^3 tons per year. But also alkynes, alkenes, esters, and organic halides can be successfully carbonylated. More recently, cationic palladium complexes with chelating bisphosphines have been developed that show great promise. At mild conditions, exceedingly high selectivities as well as high activities can be achieved and commercialization of this technology has been announced. Amidocarbonylation to produce amino acid derivatives is another technology that has found great interest and carbonylation of aromatic halides is about to establish itself as a standard procedure for pharmaceutical intermediates. The updated article on carbonylation covers the major developments in this field.

1. Introduction

Reactions with carbon monoxide [*630-08-0*] rank among the most selective methods of catalytically introducing oxygen-containing functional groups into organic substrates. Walter Reppe at BASF introduced the term *carbonylation* to describe a number of reactions he discovered from 1938 onward [1 – 3]. Since then, any reaction in which carbon monoxide, alone or together with other components (e.g., water, alcohols, or amines), is introduced into an organic molecule in the presence of a catalyst is called carbonylation. Organic substrates can be unsaturated or saturated; in the second case they must contain functional groups such as hydroxyl, alkoxycarbonyl, amino, or halogen.

Carbonylation covers a wide variety of reactions. They may be classified into (1) Reppe reactions, (2) hydroformylations, and (3) Koch carbonylations.

Reppe Reactions. The term Reppe reactions describes reactions of organic substrates with carbon monoxide, sometimes in the presence of nucleophiles that contain acidic hydrogen; these reactions are catalyzed by metal carbonyls or their precursors. The reaction of unsaturated compounds with carbon monoxide and water is also known as *hydrocarboxylation*; similarly, that of carbon monoxide and alcohols is known as *hydroesterification*.

The Reppe reactions yield carboxylic acids, esters, anhydrides, amides, lactones, and isocyanates. Starting materials are alkynes, alkenes, esters, alcohols, organic halides, ethers, lactones, aldehydes, amines, or aromatic nitro compounds. Many of the carbonylation reactions of unsaturated compounds also require nucleophiles containing acidic hydrogen, such as water, alcohols, ammonia, amines, thiols, or carboxylic acids [4].

Hydroformylation. In 1938 Otto Roelen at Ruhrchemie discovered the synthesis of aldehydes and alcohols from olefins, carbon monoxide, and hydrogen. This reaction has for historical reasons always been treated separately as *hydroformylation* or *oxo synthesis*. Although it is covered by the generic term carbonylation, it is not treated in this article (→ Aldehydes, Aliphatic and Araliphatic; → Oxo Synthesis).

Koch Carbonylation. The carbonylation of olefins, alcohols, or aldehydes, by using strong acids such as H_2SO_4, $H_3PO_4 - BF_3$, or $HF - SbF_5$ as catalysts, is known as the Koch synthesis (also called Koch-Haaf reaction) [4, pp. 123 – 146], [5]. It yields predominantly branched isomers of carboxylic acids: *Neo Acids* (Exxon), *Versatic Acids* (Resolution, formerly Shell). Du Pont has also developed a process for the production of glycolic acid based on the Koch carbonylation of formaldehyde. The economic importance of these products is far less than that of the compounds obtained by Reppe reactions; the Koch synthesis is not dealt with in this article.

Also not treated is the base-catalyzed carbonylation of alcohols or amines to yield alkyl formates and formamides. The most prominent examples are methyl formate, an intermediate for the industrial synthesis of formic acid, and dimethylformamide (→ Formic Acid).

History. Many carbonylation processes were discovered in the period 1938 – 1957 by Reppe and his collaborators at BASF, and have subsequently been developed further to industrial-scale processes. Examples are the syntheses of acrylic acid, propionic acid, and acetic acid [3].

Before the term carbonylation was introduced, reactions of olefins with carbon monoxide and water to give carboxylic acids or their esters were described in numerous patents. However, these reactions used substances of large surface area as catalyst carriers and acids such as phosphoric acid, heteropoly acids, boron trifluoride, metal halides, or similar catalysts; they required high pressures (700 – 900 bar) and high temperatures and are no longer of practical importance. Further development of these carbonylation reactions led to implementation of the Koch synthesis.

Metal carbonyls were first used as carbonylation catalysts by Reppe. Their great advantage over the older catalysts is that structural isomerization hardly takes place during the reaction. Metals of the eighth subgroup have proved to be most effective as catalysts. It was possible to optimize the catalyst metal, the ligands, and the promoters for nearly every carbonylation reaction in such a way that the reactions took place under milder conditions than previously known. Nevertheless, these processes could only be realized industrially after the development of appropriate reactor materials because of the corrosive properties of the reaction media.

2. Catalysts

Metal carbonyls or metal carbonyl hydrogen compounds or their substituted derivatives are most suitable as catalysts for carbonylation reactions. The most effective catalyst metals are Fe, Co, Ni, Ru, Rh, Pd, Os, Ir, Pt, and Cu. However, it can also be advantageous to use more readily accessible metal compounds as "precatalysts," provided that they are capable of forming metal carbonyl complexes under the reaction conditions. Examples of these are simple or complex salts (mainly halides and acetates), oxides, or the metals themselves in finely divided form. When halides are used, the nature of the halogen is often a decisive factor, especially for nickel and cobalt: the catalytic activity increases from the

chloride through the bromide to the iodide; fluorides are inactive. Table 1 gives a survey of reactants in common industrial carbonylations.

Table 1. Summary of the catalyst metals generally used for carbonylation reactions

Raw materials	Products	Catalyst metals
Alkynes	unsaturated carboxylic acids and derivatives	Pd, Ni, Fe, Co
	unsaturated acid chlorides	Rh, Ru
	unsaturated dicarboxylic acids and derivatives	Pd, Co
Alkenes	saturated carboxylic acids and derivatives	Pd, Co, Ni, Pt, Fe, Ru, Cu
	unsaturated carboxylic acids and derivatives	Pd
	alcohols	Fe
Dienes	unsaturated monocarboxylic acids or saturated dicarboxylic acids or their esters	Pd, Co, Pt
	unsaturated dicarboxylic acid esters	Pd – Cu, Pd – V, Pd – Fe
Alcohols	carboxylic acids	Rh, Ir, Co, Ni
Diols	dicarboxylic acids	Rh, Cu, Ir
Alkyl halides and aryl halides	carboxylic acids and derivatives	Pd, Rh, Ni, Co, Fe
Allyl halides	carboxylic acid halides	Pd, Ni
Ethers	carboxylic acid esters	Rh, Ni, Co, Pd, Fe
Esters	anhydrides and carboxylic acids	Rh, Ni, Co,
Aldehydes	hydroxycarboxylic acids	Ni, Co
Nitro compounds	isocyanates and ureas	Pd, Rh, Ni, Co, Fe
Amines	formamides and ureas	Co, Ni, Pd

More recent work is focused on Rh or Ir catalysts for the carbonylation of alcohols, ethers, and esters and on Pd catalysts for the carbonylation of unsaturated substrates.

The following chemical reactions always take place at the central metal in the course of the catalysis (Fig. 1):

1) With saturated substrates, oxidative addition to the metal occurs, formally increasing its oxidation state by two; with unsaturated substrates the metal hydride adds to the π-electron system. Both reactions result in the formation of a metal – carbon σ-bond.
2) The next stage is the formation of an acyl – metal intermediate by migratory insertion of CO.
3) The final stage is the reductive elimination or solvolysis of the organometallic complex to yield the product.

When optimizing the reaction conditions, one must take into account the stability of the corresponding carbonyl complex; it varies considerably with the ligands, carbon monoxide pressure and temperature [4, p. 15].

All the metal carbonyls used as catalysts for Reppe-type reactions are extremely toxic. Because of this, great care must be taken when handling these substances, especially the volatile compounds $Ni(CO)_4$, $HCo(CO)_4$, and $Fe(CO)_5$.

2.1. Nickel Catalysts

For the carbonylation of alkynes, catalysts based on nickel and hydrogen halides are found to be far superior to all other catalysts. Nickel has lost its outstanding position with the decline in the economic importance of acetylene as a feedstock, because in some cases, nickel is less effective for the carbonylation of olefins, alcohols, or organic halides than other metals.

The catalytically active species is always a substituted nickel carbonyl complex. The reaction takes place at CO pressures of ≤ 100 bar and temperatures below 250 °C; at higher pressures the formation of tetracarbonyl nickel [*13463-39-3*], $Ni(CO)_4$, results in inactivity. Because nickel carbonyls are formed extremely readily under an atmosphere of CO, it is sufficient to use binary or complex nickel salts as starting materials. The use of $Ni(CO)_4$ enables carbonylation reactions to be carried out stoichiometrically in a convenient manner without using CO [6]. The reaction mechanism of the nickel-catalyzed carbonylation of alkynes is shown in the scheme on the next page (under Fig. 1):

Figure 1. Catalytic cycle in carbonylation with saturated substrates or unsaturated substrates
R, R′ = alkyl, aryl; X = halide

Catalyst formation:

$NiX_2 + 5\ CO + H_2O \longrightarrow Ni(CO)_4 + 2\ HX + CO_2$

$Ni(CO)_4 + HX \longrightarrow HNi(CO)_2X + 2\ CO$

Carbonylation:

$HNi(CO)_2X + R{-}C{\equiv}CH \longrightarrow H_2C{=}C(R){-}Ni(CO)_2X$

$H_2C{=}C(R){-}Ni(CO)_2X + CO \longrightarrow H_2C{=}C(R){-}C(=O){-}Ni(CO)_2X$

$H_2C{=}C(R){-}C(=O){-}Ni(CO)_2X + R'OH \longrightarrow H_2C{=}C(R){-}C(=O){-}OR' + HNi(CO)_2X$

$R{-}C{\equiv}CH + CO + R'OH \longrightarrow H_2C{=}C(R){-}C(=O){-}OR'$

where X = halide; R, R′ = alkyl

When nickel halides are used as catalysts, traces of water are required to accelerate the formation of the active species. In absolutely anhydrous media, the carbonylation reaction only starts when water is formed in side reactions.

2.2. Cobalt Catalysts

The main field of use for cobalt catalysts in industrial processes is the hydroformylation of olefins under high-pressure conditions to yield aldehydes or alcohols. Cobalt catalysts may also be used for the carbonylation of monoolefins and diolefins and of alcohols to give carboxylic acids or their derivatives. The cobalt catalysts are used in the form of octacarbonyl dicobalt [*10210-68-1*], $Co_2(CO)_8$, or, as precursors of the latter, cobalt acetate or the cobalt salt of the carboxylic acid to be synthesized. The preferred reaction conditions are 150 – 250 °C and 150 – 200 bar for alkenes, and 500 bar or higher for alcohols. The active species in each case is hydrido tetracarbonyl cobalt [*16842-03-8*], $HCo(CO)_4$ [7]; the formation of this is accelerated by adding bases (pyridine, picoline, quinoline) or hydrogen:

Catalyst formation:

$2\ Co(OOCR)_2 + 8\ CO + 3\ H_2 \longrightarrow 2\ HCo(CO)_4 + 4\ RCOOH$

or

$Co_2(CO)_8 + 2\ C_5H_5N + CO + H_2O \longrightarrow 2\ C_5H_5N^+Co(CO)_4^- + CO_2$

$\Downarrow\Uparrow$

$C_5H_5N + HCo(CO)_4$

Catalytic cycle:

$HCo(CO)_4 + R'{-}CH{=}CH{-}CH_3 \rightleftharpoons$

$R'{-}CH{=}CH{-}CH_3 \rightleftharpoons R'{-}CH_2{-}CH(Co(CO)_n){-}CH_3 \rightleftharpoons$

$R'{-}CH_2{-}CH{=}CH_2 \rightleftharpoons R'{-}CH_2{-}CH_2{-}CH_2{-}Co(CO)_n \xrightarrow{CO,\ R''OH}$

$R'{-}CH_2{-}CH_2{-}CH_2{-}COOR'' + HCo(CO)_4$

where R, R′, and R″ = alkyl and n = 2 or 3

In the presence of hydrogen, hydroformylation takes place as a competitive reaction; therefore, the preforming of the catalyst with CO – H_2 often is carried out as a separate stage in industrial processes (precarbonylation) [8].

The addition of tertiary amines increases not only the reaction rate, but also the proportion of linear isomer in the product: coordination of the amine to the cobalt causes considerable steric hindrance for the further reaction of internal double bonds. As a result of this, these olefins isomerize to give α-olefins, which is also catalyzed by cobalt (for catalytic isomerization of double bonds, see Chap. 4). On the other hand, high concentrations of base suppress the carbonylation of monoolefins, because the base also competes with the alkene as a ligand.

The *carbonylation of conjugated dienes* requires a fairly high concentration of tertiary amines to break up the intermediate π-allyl complex [9]:

As the concentration of base increases, the reaction rate reaches a plateau and then remains unchanged if the concentration is increased further.

2.3. Palladium Catalysts

In general, carbonylation reactions with palladium catalysts take place under much milder conditions ($\leq$ 150 bar and 140 °C) than those with nickel or cobalt catalysts [10]. Considerable efforts have been devoted to develop more stable palladium catalysts, and the role of mono- and bidentate ligands as well as the role of coordinating and noncoordinating anions has been studied in detail [11]. Several large-scale industrial processes have been developed and palladium is the catalyst of choice for fine chemicals synthesis such as Ibuprofen. It has also helped to establish carbonylation as a standard synthetic tool in active ingredients production for agro and pharmaceuticals. Examples for Pd catalysts for the alternating polymerization of ethylene and CO to generate polyketone, for the carbonylation of alkenes, and of alkadienes are shown below.

Homogeneous catalysts based on palladium generally have a very narrow range of optimal activity and stability. Their suitability for a specific reaction depends, to a far greater extent than with the other metals, on finding a suitable combination of ligands, promoters, and solvents. The reason for this is that no simple carbonyl complexes of palladium exist, so that stabilization of the catalyst always has to be effected by adding further ligands, such as phosphines, amines, or nitriles. Furthermore, Pd^{2+} is a strong oxidizing agent, and even CO may cause its reduction to the metal, especially in an acid medium. This may be counteracted by adding such reoxidants as Cu^{2+} or Fe^{3+}.

In practice, homogeneous palladium catalysts are usually complicated multicomponent systems, and catalyst handling is problematic in continuous processes. In many cases the separation of the catalyst leads to deactivation and palladium losses. Therefore, the number of industrial processes that use palladium as the catalyst metal is still limited. To facilitate product catalyst separation the use of aqueous phase organometallic catalysis could be an option [12].

Besides the carbonylation of olefins, halides, or alcohols to carboxylic acid derivatives (see Section 4.1, Chaps. 5 and 6), palladium catalysts may also be employed for the oxidative carbonylation of monoolefins to unsaturated carboxylic acids and esters. The oxidative carbonylation of monoolefins requires a halide as promoter. In nucleophilic solvents, a stoichiometric reaction takes place in which Pd^{2+} is simultaneously reduced to Pd^0. It affords either monocarboxylic or dicarboxylic acid derivatives, the latter in the presence of strong nucleophiles (alkoxides or amines) [13]:

Table 2. Selectivity control by variation of palladium catalyst structure*

Catalyst	Ligand	Ligand structure	Substrate	Product	Ref.
	dppp		ethylene, propylene	polyketone	34
	dtbpm		ethylene, propylene	polyketone	35
	dtbpe		ethylene	diethylketone	33
	dtbpx		ethylene	methylpropionate	35
	dpa-3		ethylene	methylpropionate	33 35
	bcope		butadiene	methyl-3-pentenoate	74
$L_2Pd(S)_2^{2+}$	PPh_3	PPh_3	ethylene	methylpropionate	11
$L_2Pd(S)_2^{2+}$	2-$PyPPh_2$		propyne	methylmethacrylate	21

* S = Solvent.

where n = 1,2; NU_1 = nucleophile, e.g., alcohol
NU_2 = strong nucleophile, e.g., alkoxide or amine; R = alkyl

In the presence of an oxidizing agent, such as Cu^{2+}, Fe^{3+}, or quinones, Pd^0 is reoxidized to Pd^{2+}, and the synthesis then follows a catalytic course, provided that the oxidizing agent is in turn reoxidized with oxygen.

In weakly nucleophilic or non-nucleophilic media the addition to the double bond does not take place and unsaturated carboxylic acid derivatives are obtained [14]. This reaction is then called *oxidative carbonylation*. It may be summarized as follows:

$$R{-}CH{=}CH_2 + PdCl_2 + CO + R'OH \longrightarrow R{-}CH{=}CH{-}COOR' + Pd^0 + 2\,HCl$$

$$2\,FeCl_3 + Pd^0 \longrightarrow 2\,FeCl_2 + PdCl_2$$

$$2\,FeCl_2 + 2\,HCl + 1/2\,O_2 \longrightarrow 2\,FeCl_3 + H_2O$$

where R, R' = alkyl

The primary catalytic cycle at the palladium center includes the following steps:

An industrial application of the oxidative carbonylation is not yet in sight.

Palladium catalysts are also used for the *carbonylation of organic halides*. Normally a Pd(0) – phosphine complex, such as $Pd(CO)[P(C_6H_5)_3]_3$ or $Pd[P(C_6H_5)_3]_4$, or a complex Pd(II) halide, such as $PdCl_2[P(C_6H_5)_3]_2$ or a bis(π-allyl)palladium chloride, is employed. The carbonylation of organic iodides takes place under conditions as mild as 60 – 100 °C and 1 – 15 bar [15]; the reaction mechanism is shown below:

2.4. Rhodium and Iridium Catalysts

The preferred processes to produce acetic acid as well as acetic anhydride use noble-metal carbonylation technology. The first Rh-based process to acetic acid is known as the Monsanto process. Today, about 8×10^6 tons of acetic acid are produced by this technology and plant capacities exceeding 500 000 t/a are regarded as world scale. Anionic complexes such as $[Rh(CO)_2I_2]^-$ or $[Ir(CO)_2I_2]^-$ are used in the presence of high concentrations of methyl iodide and the oxidative addition of the latter to Rh is the rate-determining step [16]. The significant lower costs of iridium and the remarkable robustness of its carbonyl complexes have favoured its commercial application recently.

3. Carbonylation of Alkynes

3.1. Acrylic Acid from Acetylene

The first catalytic carbonylation reaction achieved by Reppe was the reaction of acetylene with CO and H_2O to give acrylic acid [*79-10-7*], using $Ni(CO)_4$ as the catalyst [17]. If water is replaced in this reaction by alcohols, thiols, secondary amines, or carboxylic acids, the corresponding esters, thioesters, amides, or mixed anhydrides of acrylic acid are obtained. In general, pressures below 100 bar and temperatures below 250 °C are required for this reaction, if such catalysts as $Ni(CO)_4$ or nickel salts (halides or complex salts) are present.

The synthesis of acrylic acid from acetylene was originally the industrially most important Reppe reaction. Since the middle of the 1960s, however, its importance has declined steadily, compared with that of the oxidation of propene [3, p. 296, 18]. An acetylene-based acrylic acid plant was operated by BASF in Ludwigshafen (110 000 t/a) until recently. It employed the catalyst system $NiBr_2$ /CuI. The synthesis took place at 100 bar and 220 – 230 °C, yielding acrylic acid with a selectivity of 90 %, based on acetylene.

The Reppe acrylic acid process is available in three versions: (1) in a stoichiometric version, in which $Ni(CO)_4$ acts as the source of CO and, together with HCl, as the catalyst; (2) in a stoichiometric – catalytic version, in which the $Ni(CO)_4$ is employed in a stoichiometric amount, but the $NiCl_2$ produced is rereduced to $Ni(CO)_4$ in an intermediate stage; and (3) in the catalytic version (BASF plant), in which the catalyst is not worked up [6]. Only the last two of these have achieved industrial importance.

3.2. Other Carbonylation Reactions of Alkynes

The carbonylation of alkynes in the presence of nickel catalysts always involves a formal *cis* addition of H and COOH to the triple bond. Markovnikov or anti-Markovnikov products result, depending on the nature of the substituent:

The homologous series of alkylacetylenes thus yields, virtually without exception, the corresponding 2-alkylacrylic acids. The yields decrease as the length of the alkyl radical increases [19]. Accordingly, the slowly reacting acetylenecarboxylates yield fumarates when a palladium compound and a hydrogen halide are used as catalysts [20].

A highly active catalyst system for the methoxycarbonylation of propyne to yield methyl methacrylate (MMA) has been developed by Drent and co-workers from Shell [21]. The cationic palladium catalyst is formed in situ from palladium acetate, an excess (10–40-fold on Pd) of a monophosphine, and a strong acid such as methylsulfonic acid. 2-Pyridyldiphenylphosphine (2-PyPPh$_2$) was the preferred ligand and at mild conditions such as 45 °C and 10 – 60 bar of CO about 40 000 mol (MMA) mol^{-1} h^{-1} (Pd) MMA were formed with a selectivity of almost 99%.

Depending on the reaction conditions and the catalysts a variety of products can be obtained from alkyne carbonylation, such as methyl 2,4-pentadienoate (**1**) [22], maleic acid esters (**2**) [23], or acetylenecarboxylic acid esters (**3**) [24]:

Polyunsaturated alkynes (enynes or diynes) react slower than simple alkynes and require drastic reaction conditions.

A few special carbonylation reactions of alkynes yield cyclic products, some of which are natural products or biologically active. Examples are the α-methylene lactone (**4**) [25] or the substituted furanone (**5**) [26, 27]:

4. Carbonylation of Alkenes

In principle, the same catalyst metals may be used for the carbonylation of alkenes as for the carbonylation of alkynes, but higher temperatures and pressures are required. In contrast to alkyne carbonylation, the advantages of nickel as the catalyst metal are much less pronounced in alkene carbonylation. Cobalt, palladium, platinum, rhodium, and ruthenium give equally good or even better results [28]. The reaction conditions, yields, and selectivities can be influenced to a considerable extent by the choice of ligands and promoters.

Selectivities are in most cases markedly inferior to those of alkyne carbonylation. Usually mixtures of carboxylic acids or esters are obtained. The reason for this is isomerization of the olefinic substrate, because all carbonylation catalysts isomerize olefinic double bonds to some extent [29].

Nickel has the smallest isomerization activity. The product mixture obtained reflects almost exclusively the initial position of the double bond. If α-olefins are used, the introduction of the functional group into the 2-position is slightly preferred (60 %) over the 1-position (40 %) [30].

Cobalt is a much better isomerization catalyst than nickel. When the cheaper internal olefins or olefin mixtures are carbonylated, the products are mainly derived from the terminal olefin regardless of the position of the double bond in

the substrate. In contrast to nickel, the carbonylation introduces the functional group mainly into the 1-position [30], and the linear carboxylic acid, for example, predominates in the product mixture (*n*-fraction: 55 – 60 %).

The proportion of linear product can be increased to over 80 % by adding bases (bulky ligands, such as pyridine or picoline; cf. Section 2.2) [31].

In the presence of *palladium* and *platinum* catalysts, the reactions take place at moderate temperatures (below 140 °C); this facilitates the carbonylation of substrates that are sensitive to polymerization, such as butadiene or styrene. However, platinum catalysts are only effective for α-olefins [32]. As mentioned earlier, considerable progress has been achieved in the improvent of palladium catalysts (see also Table 2). For instance, complete product selectivity control has been achieved in the methoxycarbonylation of ethylene [11, 33, 34]. Cationic palladium complexes with monodentate ligand such as PPh_3 or chelating ligands with bulky substituents such as 1,3-bis(di-1,3,5,7-tetramethyl-2,4,8-trioxa-6-phospha-adamant-6-yl)propane (dpa-3), 1,3-bis(di-*tert*-butylphosphino)propane (dtbpp) or 1,2-bis(di-*tert*-butylphosphinomethyl)benzene (dtbpx) yield with very high activity methylpropionate with a selectivity exceeding 99%. *Diethyl ketone* is obtained, when 1,2-bis(di-*tert*-butylphosphino)ethane (dtbpe) is used in the presence of strong acids. However, if 1,3-bis(diphenylphosphino)propane (dppp) or 1,1-bis(di-*tert*-butylphosphino)methane (dtbpm) is used to generate the cationic complexes, *polyketone*, a perfect alternating copolymer of ethylene and CO, precipitates as a snow white solid. Molecular masses (M_r) of about 20 000 g/mol are achieved and more than 10^6 moles of ethylene per mole of Pd are converted. The influence of ligands to control carbonylation selectivity has been reviewed [35]. Palladium catalysts with chelating phosphines have also been developed for the isomerizing carbonylation of internal olefins, introducing the carboxylic acid into the 1-position with high selectivity (97 %) [36].

For the palladium catalyzed carbonylation of unsaturated substrates, formic acid, oxalic acid, as well as alkyl formates have been proposed as the carbonylating agent, replacing carbon monoxide [37].

Simple or complex *rhodium* and *iridium* salts, such as those containing tertiary phosphines as ligands, also catalyze the carbonylation of olefins in the temperature range 100 – 130 °C and at a pressure of 1 bar or more [29, 38].

In general, hydroesterification (CO + ROH) takes place more slowly than hydrocarboxylation (CO + H_2O). The opposite applies to palladium catalysts, however. The reactivity of the olefin decreases as the degree of branching and substitution increases. Therefore, tetraalkylethylenes cannot be carbonylated by the Reppe reaction. Under the conditions of the Koch synthesis, however, they are readily carbonylated [4, pp. 123 – 146].

The reaction of olefins with carbon monoxide and alcohols can be accelerated by adding hydrogen, water (formation of hydrogen by the shift reaction), or acids (carboxylic acids having up to three carbon atoms or a hydrogen halide). These additives promote the formation of the carbonyl hydride, which is the real effective catalyst.

In the presence of nucleophiles other than water or alcohols, acid chlorides, amides, thioesters, or anhydrides are obtained:

4.1. Monoalkenes

Ethylene. Catalytic carbonylation of ethylene [*74-85-1*] in the presence of water and nickel propionate gives propionic acid [*79-09-4*] in a yield of 95 %. The following process is operated by BASF: 200 – 240 bar, 270 – 320 °C, silver-lined reactor [5, 39] (→ Propionic Acid and Derivatives). When propionic acid is used as the solvent in this reaction, the product is propionic anhydride [2, p. 38], [40]. Much milder conditions such as pressures of < 10 bar and temperatures of 100 – 150 °C can be applied, if palladium catalysts with chelating ligands such as dpa-3 are used [41]:

Lucite has developed the Alpha process to produce MMA by methoxycarbonylation of ethylene to methyl propionate followed by reaction with formaldehyde. A commercial plant with a capacity of 120 000 t/a MMA has been announced which is expected to be commissioned in 2007 in Singapore [42]:

The oxidative carbonylation of ethylene using a $PdCl_2$ – $CuCl_2$ catalyst in acetic anhydride yields a mixture of acrylic acid [*79-10-7*] and β-acetoxypropionic acid [*4272-12-2*]; the second can be converted into acrylic acid by heating [43, 44]. If this reaction is carried out in the presence of secondary amines, acrylamides are obtained [45]. The synthesis of dialkyl succinate from ethylene using palladium catalysts takes place in the presence of a nucleophile, cf. Section 2.3:

When $Co_2(CO)_8$ is used as catalyst, diethyl ketone [*96-22-0*] is obtained from ethylene and carbon monoxide in the presence of a hydrogen donor at 165 °C and 70 bar in a yield of 97 % [46]. A very efficient diethylketone synthesis is achieved at 40 bar CO/H_2 (1:1) with a $Pd/MeSO_3H$/dtbpe catalyst [33]. At a rate of 80 000 mol mol^{-1} h^{-1} (Pd) the diethylketone selectivity reaches 98%.

A further reaction of ethylene leads to five-membered cyclic lactones (100 – 200 °C; 600 – 800 bar). The catalyst is a palladium compound in combination with a hydrogen halide. The yields of the products **6, 7,** and **8** in this reaction depend on the conditions. At elevated temperature lactone **7** is formed preferentially [48]:

6 3–Hexen–1,4–olide **7** 2–Hexen–1,4–olide **8** 4–Hexen–1,4–olide

Palladium and chelating phosphines are equally very efficient catalysts for the strictly alternating copolymerisation of ethylene and carbon monoxide. The synthesis of polyketone by use of cationic palladium/dppp catalysts has been scaled up by Shell into a commercial operation of about 20 000 t/a. The polymer was intended to serve the engineering plastics market due to its excellent high temperature properties which could be adjusted by using mixtures of ethylene and propene as the olefin. Unfortunately, market success did not meet the expectations and the plant was dismantled. The same process was studied by BP at pilot plant scale.

The same kind of catalytic systems (a palladium(II) precursor, a chelating phosphine and an acid) in methanol as the solvent can thus lead very selectively to methyl propionate or to polyketone. The selectivity of this transformation is controlled by the substitution scheme of the chelating phosphine [35].

Propene. Depending on the catalyst, isobutyric acid [*79-31-2*] and butyric acid [*107-92-6*] are obtained in varying proportions when propene [*115-07-1*] is carbonylated [49]:

Carbonylation in the presence of methanol with ruthenium carbonyls as catalyst at 190 °C and 20 bar gives a mixture of methyl butyrates, the proportion of the linear isomer being less than 50 % [50].

The carbonylation of propene to give isobutyrates, with subsequent dehydrogenation by means of sulfur [51], I_2– O_2 [52], or O_2 [53], may offer a commercially interesting route to methyl methacrylate [*80-62-6*]:

The *synthesis of butanol* from propene and CO is not a carbonylation, but a hydroformylation reaction, according to the definition given in Chapter 1. However, it is often mentioned in connection with Reppe reactions. This synthesis yields a mixture of 85 % of 1-butanol [*71-36-3*] and 15 % of 2-butanol [*78-92-2*] from propene; the catalyst is $H_2Fe(CO)_4$ in *N*-butylpyrrolidine; conditions: 100 °C and 15 bar. The butanol process is no longer operated, but some successful attempts have been made to generalize this reaction by adding a rhodium compound to the catalyst.

Styrene. Because of its strong tendency to polymerize, styrene [*100-42-5*] must be carbonylated at temperatures around 100 °C. Cobalt and palladium catalysts are sufficiently active within this temperature range. The products formed depend considerably on how the palladium catalyst is modified [54]:

Heptene and Octene. When $SnCl_2$ – $PdCl_2[P(C_6H_5)_3]_2$ is used as catalyst at 70 °C and 140 bar, 1-heptene [*592-76-7*], carbon monoxide, and methanol yield a mixture of methyl octanoates with a 93 % fraction of the linear isomer [*111-11-5*] [55]. The analogous reaction of 1-octene [*111-66-0*] using $FeCl_2$ – $PdCl_2$ as catalyst gives 1-nonanoate [*1731-84-6*] and 2-nonanoate [*2177-86-8*] in a ratio of 4 : 5 [56]. Higher olefins can be alkoxycarbonylated with regioselectivities exceeding 99 % to the linear alkyl caboxylates by use of cationic Pd/dtbpx catalysts [36, 57]:

Surfactant Alcohols from Higher Olefins. The Reppe butanol synthesis cannot be applied to long-chain olefins containing nonterminal double bonds. However, a simple route to the esters of long-chain carboxylic acids is afforded by the carbonylation of these olefins in the presence of cobalt salts of fatty acids in combination with pyridine or β-picoline at about 170 °C and 130 bar [58]. This yields the corresponding methyl carboxylates, which can then be hydrogenated to surfactant alcohols; the proportion of linear isomers is 79 % and the overall conversion 70 – 80 % [59]. This route could develop into an economic alternative to the conventional oxo process.

4.2. Substituted Alkenes

Unsaturated Amides. Carbonylation of unsaturated amides in the presence of cobalt

catalysts affords five- or six-membered cyclic imides:

Unsaturated Amines. When unsaturated amines are carbonylated in the presence of $Co_2(CO)_8$, *N*-alkyl pyrrolidinones are obtained. Carbonylation of allyl halides in the presence of primary amines and a rhodium compound affords the same products [60]:

Unsaturated Alcohols. Five- or six-membered lactones are obtained by carbonylation of unsaturated primary alcohols [4]:

Unsaturated Esters, Acids, and Nitriles. 3-Pentenoic esters as well as pentenoic acid can be obtained by carbonylation of butadiene (see below). 3-Pentennitrile is the primary product of the first stage of butadiene hydocyanation to yield adipodinitrile, a process carried out at large scale at Invista, formerly Du Pont. These substrates can be carbonylated at surprisingly mild conditions (below 10 bar) to yield almost quantitatively (>98 %) the linear difunctional products dialkyladipate, adipic acid, and 5-cyanoalkylvalerate, respectively. The nitriloester can be hydrogenated to yield ε-caprolactam. Thus, these carbonylations are interesting routes to produce nylon intermediates [36, 61, 62] (see bottom of page).

Carbonylation of Oleic Acid. A mixture of isomers composed of 2-octyl-1,9-nonanedicarboxylic acid (**9**), 2-nonylsebacic acid (**10**), and 2-heptyl-1,10-decane-dicarboxylic acid (**11**) is obtained, in a yield of over 90 %, from oleic acid, carbon monoxide, and water in the presence of $Ni(CO)_4$ and iodine as catalyst. Isooleic acid and undecylenic acids react similarly [2, p. 38].

4.3. Polyenes

Butadiene. Temperatures above 140 °C are required for adequate activity of the *nickel catalysts* in the carbonylation of butadiene [*106-*

99-0]. However, at these temperatures butadiene dimerizes to a high degree to give 4-vinylcyclohexene or polymerizes in the course of the reaction. For this reason the carbonylation gives a mixture of branched and straight-chain monocarboxylic and dicarboxylic acids derived from vinylcyclohexene [2, p. 38] [40].

The reaction takes place at lower temperatures if *palladium catalysts* are used [13, 63]. 3-Pentenoyl chloride [*17066-20-5*] and Pd^0 are obtained from butadiene and CO in a stoichiometric reaction catalyzed by $PdCl_2$.

In the presence of alcohols, the catalytic reaction gives C_5 or C_9 esters, depending on the catalytic system:

The nature of the anion determines the products formed in an extremely selective manner [64]. Halides prevent the palladium-catalyzed dimerization of butadiene. The addition of nitrogen bases (pyridine, alkylamines) [65], tetraalkylammonium, or tetraalkylphosphonium salts [66] increases the activity of the catalyst.

The use of palladium halides in combination with hydrogen halides increases both the life of the catalyst and the activity of the system. Palladium chloride is preferred; although it has a lower activity than the bromide or iodide, it displays the highest selectivity to the 3-pentenoic acid ester [67]. However, the initial high activity of the catalyst is only retained for a short period, and considerable loss of palladium takes place.

Carbonylation in the presence of water gives the free carboxylic acids. As a rule, higher temperatures are necessary for this reaction. 3-Pentenoic acid [*5204-64-8*] is obtained in a 70 % yield when $Co_2(CO)_8$ – pyridine is used at 160 °C and 250 bar [68], or in an 86 % yield when a palladium compound is used in the presence of tetraalkylammonium salts at 100 °C and 145 bar [69].

A mixture of 4-pentenoic and 3-pentenoic acid esters, in which the 4-isomer predominates, is obtained by means of *rhodium catalysts* [70]. The carbonylation of butadiene or substituted butadienes to give pentenoic acid esters takes place with very high regioselectivity, at 120 – 140 °C and above 200 bar, when *cobalt catalysts*, e.g., $Co_2(CO)_8$ and such nitrogen bases as pyridine, picoline, or isoquinoline are used as catalysts. The selectivity of the system increases as the pyridine concentration is increased (for the reaction mechanism, see Section 2.2). The reactivity decreases in the following series:

The double carbonylation of butadiene to give adipic acid [*124-04-9*] or its esters is described by many authors. Rhodium catalysts (yield 40 %) [71] or cobalt catalysts [72] are suitable. However, the drastic conditions (200 – 250 °C, 250 – 300 bar) required for this one-stage synthesis are very detrimental to selectivity.

On the other hand, a two-stage process using cobalt catalysts has been developed at pilot plant scale by BASF. It offers a route to adipic acid from the butadiene-containing C_4 cut [9, 73]:

The advantage of this high-pressure two-stage process is that it is possible to optimize both the reaction conditions and the catalyst to suit the individual reactions. The *first stage* requires fairly high concentrations both of cobalt and of pyridine to ensure adequately rapid carbonylation of butadiene; at the same time the temperature may be kept low and both the reaction rate and the selectivity increase as the pressure increases. In the *second stage* the concen-

tration of pyridine must be low because it has an inhibitory effect on the carbonylation of the pentenoic acid ester. The 3-pentenoic acid ester rapidly isomerizes to form the 4-pentenoic acid ester under the conditions of the second stage. Dimethyl adipate [*627-93-0*] is formed with an overall selectivity of ca. 70 %. The catalyst precursor employed is a cobalt carboxylate, from which the actual catalyst, in both stages $HCo(CO)_4$, is formed.

More recently, improved cationic palladium catalysts have been developed both for the methoxycarbonylation [74] and hydroxycarbonylation of butadiene [75] running at pressures of about 50 bar. While Pd/bcope is suited for alkoxycarbonylation, Pd/dtbpx is the preferred catalyst for hydroxycarbonylation. Since the latter catalyst can also be used at reduced pressure for 3-pentenoic acid hydroxycarbonylation (see above), both stages of adipic acid synthesis can be carried out without change of the catalyst system. Adipic acid can be removed from the product mixture by filtration and the yield exceeds 90% based on butadiene. This process has been demonstrated by Shell at laboratory scale.

The *oxidative carbonylation* of butadiene using palladium catalysts takes place at moderate temperature.

The palladium(0) formed in the reaction is reoxidized by Cu^{2+}, Fe^{3+}, or V^{5+}; enol ethers, acetals, or ketals are employed to bind the water of oxidation, which is harmful to the catalyst [76]. However, the life of the catalyst is short, and there is considerable formation of byproducts.

Acetyldienes are formed from butadiene, CO, and methyl iodide in the presence of $NaCo(CO)_4$ or $Co_2(CO)_8$ by phase transfer catalysis under ambient reaction conditions [27]:

Allenes. In the presence of ruthenium carbonyls, allene [*463-49-0*] gives methyl methacrylate [*80-62-6*] or dimethyl 1,1-dimethyl-3-methyleneglutarate [77]:

The carbonylation of tetraphenylallene gives a mixture of 1,1,3-triphenylindene (**12**), 2-diphenylmethyl-3-phenylindone (**13**), and 2,2,4-triphenylnaphthalenone (**14**) [4].

Nonconjugated Polyenes. The carbonylation of nonconjugated dienes using $HCo(CO)_4$ as catalyst gives mixtures of unsaturated and saturated ketones [4]; the overall product yields depend on the distance between the double bonds in the polyene. The reaction proceeds most advantageously if the double bonds are separated by one or two carbon atoms:

In palladium-catalyzed reactions with CO in the presence of water or alcohols, nonconjugated dienes behave like monoolefins: the double bonds are carbonylated independently and successively [78]:

where R = alkyl

1,5,9-Cyclododecatriene [*2765-29-9*] cannot be carbonylated by conventional methods (high temperatures); instead, ring-contraction products are obtained. Only palladium catalysts can be used under conditions sufficiently mild to enable one, two, or all three double bonds to be carbonylated [10].

5. Carbonylation of Alcohols and Ethers

The carbonylation of alcohols to give carboxylic acids is by far the most important application of carbonylation in industry. The most important individual reaction of this type is the synthesis of acetic acid [*64-19-7*] from methanol. World production of this chemical is at present about 10×10^6 t/a. The bulk of this is obtained by the carbonylation of methanol, using rhodium or iridium catalysts based on the Monsanto process (→ Acetic Acid). In addition, the cobalt-catalyzed BASF process is still carried out at a relatively small plant in Ludwigshafen.

5.1. BASF Acetic Acid Process

The BASF process was optimized at the beginning of the 1950s. It requires high pressures (> 500 bar) and temperatures of about 250 °C [79]. The catalyst precursor is cobalt iodide [*15238-00-3*], CoI_2, and HI (or the less corrosive KI) in water. $Co_2(CO)_8$ is formed in the course of the reaction, and is then converted to $HCo(CO)_4$ in the presence of hydrogen (formed in side reactions). The active catalytic system is the combination of $HCo(CO)_4$ and HI [80]:

The high pressure is required to favor reaction (a), which yields the product, over reaction (b), which deactivates the catalyst.

In the past, some research work was carried out by BASF and Shell with the aim of reducing the temperature to 80 – 200 °C and the pressure to 70 – 300 bar [81].

5.2. Monsanto and Related Low-Pressure Acetic Acid Processes

The Monsanto low-pressure process was optimized in the mid-1960s. It uses a rhodium catalyst [82]. At present, about 75 % of the world's acetic acid is made by this process or by processes derived therefrom; the fraction is increasing, because further plants using this technology will start up in the next few years [83].

The process operates under very mild conditions. The reaction already takes place at a CO pressure of 1 bar, but commercial plants use a pressure of 30 bar and a temperature of approximately 175 °C. The selectivity is 98 %, based on methanol, which is unusually high for catalytic reactions.

The kinetics have been investigated in detail and were shown to depend first order on methyl iodide and rhodium/iridium concentration. Remarkably, neither methanol nor CO partial pressure are part of the rate law [84]. The oxidative addition of methyl iodide to Rh^+ constitutes the rate determining step. In addition, the iodide has the function of protecting Rh^+ against reduction by CO [85]. The following mechanism has been proposed for this reaction:

One problem of the Monsanto process is the high methyl iodide concentration required in the process. Therefore, numerous attempts have been made to absorb the rhodium onto carriers and to employ it in a halogen-free form, but it proves to be a poor heterogeneous catalyst [86]. On the other hand, nickel on zeolites or activated carbon gives a 95 % yield of acetic acid at 300 °C and 11 bar [87].

The most successful Monsanto process uses anionic rhodium iodide carbonyl complexes in the presence of large amounts of methyl iodide at water concentrations of at least 8 % to avoid catalyst decomposition and formation of insoluble rhodium salts. Unfortunately, the rhodium complexes applied also catalyze the water gas shift reaction, which results in loss of CO and side product formation such as acetaldehyde derivatives and propionic acid. Further developments have led consequently to the "low-water" processes, working at below 8 % water [16, 88]. These processes feature increased space–time yields and further improved selectivities. The Cativa process patented by BP used iridium catalysts, promoted by a second metal carbonyl, probably ruthenium. It is speculated that the role of the promoter is to abstract iodide to form a neutral iridium acetyl intermediate. In the Celanese low-water process, lithium iodide is used to stabilize rhodium at low water conditions and this is also the case in the acetic anhydride process by Eastman chemicals. A joint development by UOP and Chiyoda has led to a liquid phase process utilizing a heterogeneous polyvinylpyridine supported rhodium iodide catalyst [89].

5.3. Carbonylation of Other Alcohols and Ethers

In general, the carbonylation of primary and secondary alcohols takes place with good yields. Tertiary alcohols mainly yield olefins, as a result of dehydration. Diols may also be carbonylated to give the corresponding dicarboxylic acids or esters, but as a rule, in poorer yields and selectivities than monoalcohols. Branched isomers, monocarboxylic acids, hydroxycarboxylic acids, or lactones are formed as byproducts. Table 3 gives a survey of further carbonylation reactions of alcohols; see also [4, p. 116].

The oxidative carbonylation of methanol has found industrial application. The CuCl-catalyzed synthesis of dimethyl carbonate by the Enichem process is used at Ravenna, Italy, and at Chiba, Japan, with a combined capacity of 20 000 t/a. The product from the latter plant is used to generate diphenyl carbonate, an intermediate in the polycarbonate process by General Electric [44].

Ube Industries has perfected a process for the oxidative coupling of CO to give oxalic acid esters [90]. Although this is not a Reppe carbonylation in the classical sense, the reaction is related to the oxidative carbonylation of olefins (see Section 2.3). Alkyl nitrites are used as the oxidizing agent in the process; this avoids the handling of molecular oxygen. The synthesis is carried out in the presence of homogeneous [91] or heterogeneous [92] palladium catalysts at 70 °C and 60 – 70 bar; it yields dimethyl oxalate [*553-90-2*] or dibutyl oxalate [*2050-60-4*] in a selectivity of 95 %:

Hydrogenation of the oxalate affords a potential route to ethylene glycol [*107-21-1*], independent of ethylene.

Allyl Alcohol. The carbonylation of allyl alcohol [*107-18-6*] using palladium catalysts in the presence of alcohols gives 3-butenoic acid esters [93]. In the absence of alcohols, allyl vinylacetate [*1745-31-9*] is obtained in 88 % yield at 80 °C and 200 bar, when a catalyst containing $PdCl_2$, $P(C_6H_5)_3$, and $SnCl_2$ [60] is used:

Table 3. Carbonylation of alcohols

Alcohol	Catalyst	Reaction conditions	Product (yield)
CH_3OH	Ni/I_2	50 – 150 bar, 150 – 280 °C	CH_3COOH (95 %)
C_2H_5OH	Ni/I_2	120 bar, 250 °C	C_2H_5COOH (76 %)
$(CH_3)_2CHOH$	Ni/I_2	300 bar, 300 °C	isobutyric acid (68 %)
$C_6H_5CH_2OH$	Rh/I_2	71 bar, 175 °C	phenylacetic acid (83 %)
$HOCH_2CH_2OH$	$Ni(CO)_4/I_2$	200 bar, 250 °C	succinic acid (15 %)
$HO(CH_2)_4OH$	$Ni(CO)_4/I_2$	200 bar, 260 °C	adipic acid (69 %) *
$HO(CH_2)_4OH$	$RhCl_3/HI$	70 bar, 200 °C	adipic acid (38 %) *
$HO(CH_2)_5OH$	$Ni(CO)_4/I_2$	200 bar, 250 °C	pimelic acid (94 %) *
$HO(CH_2)_6OH$	$Ni(CO)_4/I_2$	200 bar, 260 °C	suberic acid (90 %) *

* Including the branched isomers.

Benzyl Alcohols. An industrial benzyl alcohol carbonylation is the Ibuprofen synthesis which is often cited as a textbook example of green chemistry because of its atom efficiency. The process was developed in a joint venture by Hoechst-Celanese and Boots and is now operated by BASF. The feedstock is isobutylbenzene which is acylated in the para position with acetic anhydride by use of HF as the catalyst. The corresponding acetophenone is hydrogenated to the benzyl alcohol which is carbonylated by use of $PdCl_2/PPh_3$ in concentrated HCl. This process is carried out at a scale of >3000 t/a at Bishop/Texas and is the most important synthesis of the inflammatory drug Ibuprofen [94].

Aliphatic Ethers. When symmetrical aliphatic ethers react with carbon monoxide, the corresponding carboxylic acid esters are formed; small amounts of free carboxylic acids are always present in the reaction mixture, unless the reaction is carried out under strictly anhydrous conditions. Nickel (in the form of metal, carbonyl, or complex), cobalt, or iron (in the form of salts or on carriers) can be employed as catalysts; a halide is required as promoter [3]:

Cycloaliphatic Ethers. Carbonylation of cyclic ethers leads to various products, depending on the nature of the ether [97]. Epoxides first yield hydroxycarboxylic acids [98], but these eliminate water at fairly high reaction temperatures with the formation of α,β-unsaturated carboxylic acids or esters. β-Hydroxy esters can be used to produce 1,3-diols via hydrogenation.

In absence of water or alcohols, epoxides may also be carbonylated to β-lactones. For example β-butyrolactone is obtained with high selectivity (98 %) by the carbonylation of propylene oxide catalyzed by a cobalt carbonyl complex and a Lewis acid as co-promoter ($BF_3 \cdot Et_2O$ or a Schiff base-aluminium complex) [95]. Using a cobalt carbonyl and 3-hydroxypyridine as the ligand, ethylene oxide and carbon monoxide may be copolymerized to a poly(3-hydroxypropionate) [96]. Molecular masses up to a few thousand grams per mole can be obtained.

Butyrolactone [*96-48-0*] may be obtained by carbonylation of oxetane [*503-30-0*] [97]:

The carbonylation of tetrahydrofuran [*109-99-9*] leads to adipic acid [*124-04-9*] [99] or aldehyde derivatives [100], depending on the catalytic system:

6. Carbonylation of Organic Halides

Saturated and unsaturated organic halides can be carbonylated to give carboxylic acid halides. The corresponding acids, esters, or amides are obtained in the presence of water, alcohols, or amines, respectively. In general, the reactions take place at moderate temperature (up to 150 °C) and at only slightly increased pressure; suitable catalysts are $Ni(CO)_4$, nickel(0) – phosphine complexes, palladium(0) – phosphine complexes, palladium – allyl complexes, $RhCl_3$, or $NaCo(CO)_4$. The use of $Co_2(CO)_8$ as catalyst normally requires high temperatures and pressures, but in that case, carbonylation also takes place under conditions as mild as 20 °C and atmospheric pressure if phase transfer catalysts are present [101].

The selectivity of the reactions with organic halides depends on the stability of the carbon – halogen bond to cleavage into radicals [102]. The reaction of these radicals with the solvent and radical recombinations lead to further byproducts in addition to those of the carbonylation reaction (ketones, diketones, and aldehydes) [103]. Due to the mild conditions that can be applied with palladium catalysts, this method has found increasingly application in fine-chemical synthesis [104, 105]. Gaseous carbon monoxide can be at least partially replaced by use of formic acid or formates as the carbonylating agent [106].

6.1. Aryl Halides

In the presence of such bases as $Ca(OH)_2$, aryl halides are converted into the calcium salts of the corresponding aromatic carboxylic acids. Reaction conditions are as mild as atmospheric pressure and 100 °C in polar, aprotic solvents, such as dimethylformamide (DMF) or dimethyl sulfoxide (DMSO), if $Ni(CO)_4$ is the catalyst. The reaction also takes place in less polar solvents, but it then requires higher temperatures and pressures. In tetrahydrofuran (THF), benzil [*134-81-6*] is obtained in 80 % yield. Phthalic anhydride [*85-44-9*] and benzene [*71-43-2*] are formed from bromobenzene in the presence of $Ni(CO)_4 - Na_2CO_3$ [107]:

Aroyl halides are obtained in high yield at 80 bar and 160 °C when palladium halides are used as the catalyst [108]. In the presence of water, alcohols, or amines, aryl halides are also carbonylated to aryl carboxylic acids, esters, or amides by using palladium catalysts with chelate phosphines as the ligand. A stoichiometric amount of base (or preferably in excess) is necessary to capture the hydrogen halide formed by the reaction. The order of reactivity of aryl halides is directly correlated to the strength of the aryl–halide bond (bond dissociation energy): ArI > ArBr > ArCl. Aryl fluorides are unreactive. The reactions conditions are quite mild: less than 30 bar and < 150 °C. Aryl halides substituted by

electron attracting groups are by far more reactive than those substituted by electron donating groups, since the rate-determining step of the reaction is usually the oxidative addition of the aryl halide to the Pd(0)–phosphine complex.The progress in aryl halide carbonylation has been reviewed by Beller [109 – 111].

6.2. Alkyl Halides

Alkyl halides react with carbon monoxide only in strongly polar solvents such as dimethylformamide or ethanol [112]. In general, alkyl halides are appreciably more difficult to carbonylate than aryl halides.

The carbonylation of benzyl halides is easier than that of alkyl halides but not as easy as that of aryl halides. With $Ni(CO)_4$ as catalyst, it has been thoroughly investigated; the products depend very much on the solvent [113]:

A catalytic process for the synthesis of phenylacetic acid [*103-82-2*] from benzyl chloride uses $Ni(CO)_4$ as catalyst. The product is formed with a selectivity of 95 % at 60 bar and 80 °C [114]. Phenylacetic acid or its esters can be made under even milder conditions when $[Fe(CO)_3NO]^-$ is used as the catalyst; yields between 80 and 90 % are achieved at 1 – 10 bar and temperatures below 80 °C [115]. In the laboratory phenylacetic acid esters can be made from substituted or unsubstituted benzyl halides with very high yields under catalysis by rhodium and aluminum alkoxides [116]. A process in which $Co_2(CO)_8$ and sodium methoxide are used as the catalyst is carried out on an industrial scale at 10 bar and 50 – 60 °C [112, 117]. α-Chlorocarboxylates are carbonylated to dicarboxylates by using $Co_2(CO)_8$ as the catalyst in the presence of a stoichiometric amount of base (potassium carbonate, sodium alkoxide). Dynamit Nobel has developed a synthesis of dimethyl malonate based on the carbonylation of methyl chloroacetate; this process runs under mild conditions (<100 °C, <20 bar CO) with a good selectivity (95 %). Dialkyl malonates and alkyl phenylacetates are produced by these carbonylation processes at a scale of several thousand tons per year:

The formation of phenylpyruvic acid [*156-06-9*] from benzyl chloride in a yield of 82 % is a rare example of a double carbonylation [118]:

Primary alkyl bromides can be carbonylated to give aldehydes in over 90 % yield when $Na_2Fe(CO)_4 - P(C_6H_5)_3$ is used as catalyst; secondary halides and benzyl halides react less readily [119]. With the same catalyst, it is also possible to couple different alkyl halides to give unsymmetrical ketones; stoichiometric amounts of $Na_2Fe(CO)_4$ are required in this case [120].

6.3. Allyl Halides and Vinyl Halides

When various catalysts are used, the carbonylation of allyl halides or allyl acetate in the presence of an alcohol gives high yields of 3-butenoic acid esters [121]. In the presence of ethylene, carbonylation is accompanied by chain-lengthening [122]:

A similar insertion reaction employing butadiene is catalyzed by palladium (70 °C; 40 –50 bar); it gives 3,7-octadienoic acid chloride or ester [123]. If allyl derivatives are carbonylated in the presence of acetylene by means of $Ni(CO)_4$ and water or methanol at 20 °C, the acetylene adds onto the allyl halide and 2-*cis*-5-dienoic acids or esters [124] or sorbic acid esters [125] are obtained.

On the other hand, 2-cyclohexen-1-one [*930-68-7*] and phenol [*108-95-2*] are formed if the same reaction is carried out without the alcohol in aprotic solvents. If catalytic amounts of HCl are added, allyl alcohol, allyl ethers, or allyl esters can be used as the starting material instead of allyl halides in the reactions mentioned above.

A mixture of 1-chloro-2-butene and 3-chloro-1-butene gives 3-pentenoyl chloride [*17066-20-5*] in a virtually quantitative yield, when palladium – allyl complexes in benzonitrile are used as catalyst [126].

Vinyl Halides. Carbonylation of the double bond to give 2-chloropropionates takes place predominantly when unmodified rhodium or palladium catalysts are used. Carbonylation of the carbon – halogen group, however, which leads to acrylic acid esters, takes place when the catalyst is $Ni(CO)_4$ or a palladium compound together with $P(C_6H_5)_3$ in the presence of proton scavengers (amines or alkoxides) [60, 127]:

7. Other Carbonylation Reactions

7.1. Amines

Carbonylation of primary and secondary aliphatic or aromatic amines normally gives a mixture of *N*-formyl derivatives and ureas [128]. In the case of aliphatic amines, the product ratio can be controlled by varying the reaction conditions. With the exception of osmium and iridium, all metals of the eighth subgroup have been found suitable as catalysts for this reaction. The following equations show how the product distribution depends on the catalytic system [129 – 131]:

Catalyst	A	B	
$[Rh(CO)_2Cl]_2$	35	: 65	
$[Rh(CO)_2Cl]_2/P(CH_3)_3$ (1:6)	100	: 0	
Se	0	: 100	[102]

When *tertiary amines* are carbonylated, aliphatic and aromatic amines give different reaction products. Aliphatic amines yield *N*-formyl derivatives, with the elimination of olefin, whereas aromatic amines produce carboxamides [132]. Tetracarbonyl nickel or complex nickel or cobalt compounds, such as $(NR_4)_2CoBr_4$ or $(PR_4)_2CoBr_2I_2$ (R = alkyl), are suitable as catalysts. Temperatures range from 100 to 250 °C; pressures are 100 – 700 bar.

where R^1, R^2, R^3 = alkyl

where Ar^1, Ar^2, Ar^3 = aryl

Carbonylation by means of enneacarbonyl diiron [*15321-51-4*], $Fe_2(CO)_9$, in a stoichiometric reaction offers a route to isocyanates starting from *N,N*-dichloroamines or *N,N*-dichloroamides [133] . The oxidative carbonylation of amines, using Pd^{2+} – Cu^{2+} catalysts, to give ureas [14] or formamides [134] is more favourable thermodynamically than the nonoxidative reaction. The catalytic cycle is maintained by reoxidizing Pd^0 by means of air in the presence of Cu^{2+}.

These reactions are of importance as potential routes to isocyanates; however, the yield of urea and formamide conversion to isocyanates is not yet satisfactory [135, 136]. The direct catalytic carbonylation of primary amines to give isocyanates, using $PdCl_2$ as catalyst, has also been described [134], but this reaction takes place very slowly and with poor yields. At present, all routes to isocyanates via oxidative carbonylation of amines appear less promising than those in which nitro compounds are used as the starting material (see following Section).

7.2. Aromatic Nitro Compounds

Dinitrotoluene (the mixture of 2,4- and 2,6-isomers) or nitrobenzene are used as educts for carbonylation reactions carried out with the aim of producing toluylene diisocyanate (TDI) [*26471-62-5*] or methylene di(phenylisocyanate) (MDI) [*101-68-8*], respectively. The overall reaction takes place as follows:

Both single-stage processes, in which isocyanates are synthesized directly from aromatic nitro compounds, and two-stage processes, in which urethanes are intermediates, have been described [137]. At present the two-stage processes is more promising. The single-stage synthesis requires pressures of over 200 bar and temperatures between 190 and 200 °C. A high concentration of catalyst is required. The most active catalysts are a combination of a palladium compound, a nitrogen donor ligand, and a Lewis acid. Thus, when a catalyst system containing $PdCl_2$, quinoline, and $GeCl_4$, is used, toluylene diisocyanate is obtained from dinitrotoluene with a selectivity of 60 % [138]. Rhodium, nickel, cobalt, or iron have also been described as catalysts [139].

The advantages of the two-stage process are the milder conditions required (170 °C; 100 – 150 bar) and, particularly, the fact that the carbonylation stage requires only about one-tenth the amount of catalyst used in the single-stage process. $PdCl_2$ together with various cocatalysts [140] and selenium together with pyridine and sodium acetate or lithium acetate have been described as catalysts [141, 142]. In the case of palladium, stability problems are encountered. Selenium, on the other hand, is difficult to remove from the reaction products. The route followed by the two-stage isocyanate synthesis is shown below:

7.3. Esters

The carbonylation of carboxylic acid esters yields anhydrides, or the free carboxylic acids in the presence of water. The catalysts employed

are mainly based on nickel, cobalt, or rhodium [97]. The carbonylation of methyl acetate [*80-62-6*] to give acetic anhydride [*108-24-7*] is an important industrial reaction (→ Acetic Anhydride and Mixed Fatty Acid Anhydrides). If $[(C_6H_5)_3PC_4H_9]_2NiBr_4$ is used as catalyst, acetic anhydride is obtained at 180 – 190 °C and 650 – 700 bar in 43 % yield [143]. If nickel metal together with methyl iodide and basic cocatalysts, such as lithium acetate and lutidine [144], or a system composed of nickel, CH_3I, $Sn(CH_3COO)_2$, and CH_3COOLi [145] is employed, the reaction takes place at 180 – 200 °C and 80 bar with a yield of 60 – 70 %. Acetic anhydride can be obtained in comparable yields at 20 – 50 bar and 160 – 180 °C if $RhCl_3$ and methyl iodide as well as promoters, such as $Cr(CO)_6$, zirconium, hafnium, lithium iodide, or trialkyl arsenic [146], are used.

In 1983 Eastman Kodak started operation of an acetic anhydride plant with a capacity of 230 000 t/a, which is based on the carbonylation of methyl acetate (Halcon licence) and uses coal as the feedstock [147]. Additional capacity of 50 000 t/a will come on stream in 2008 at a acetyls plant owned by Sipchem, a joint venture in Jubail Industrial City, Saudi Arabia. This plant also uses Eastmans coproduction technology and will also produce 460 000 t/a of acetic acid. The mechanism of methyl acetate carbonylation is similar to the related methanol carbonylation. Salt promoters like LiI and a low partial pressure of H_2 are essential to maintain catalyst activity [12]. Plants utilizing the carbonylation technology for acetic anhydride are generally "swing" plants that can produce both acetic acid and acetic anhydride. BP Chemicals also operates such a plant in Hull, United Kingdom.

7.4. Lactones and Aldehydes

Lactones can be carbonylated, like cyclic ethers, to give dicarboxylic acids (see Section 5.3). They are probably formed as intermediates in the carbonylation of cyclic ethers. Glutaric acid [*110-94-1*] is obtained from γ-butyrolactone, and adipic acid [*124-04-9*] from δ-valerolactone [148].

Aldehydes. The reactions of aldehydes with carbon monoxide are hitherto limited to formaldehyde [*50-00-0*]. This reaction requires the presence of proton-donating solvents and yields glycolic acid [*79-14-1*] or its esters. The catalysts used are nickel, cobalt, or iron [149] or alumosilicates [150]. The reaction conditions are 180 – 250 °C and more than 100 bar; the selectivities achieved are higher than 90 %. A better route from formaldehyde to glycolic acid is the Koch Carbonylation (see Chap. 1) [5, p. 41].

7.5. Amidocarbonylation of Aldehydes

The cobalt carbonyl catalyzed carbonylation of aldehydes in the presence of alkylamides is a versatile route to *N*-acyl α-amino acids [137, 152]. The reaction proceeds via aminal intermediates and can be coupled with aldehyde generating reactions like hydroformylation, epoxide rearrangement, or allyl alcohol rearrangement in one stage syntheses:

Amidocarbonylation of formaldehyde yields glycine derivatives. If this reaction is carried out in the presence of *N*-methyl laurylamide, *N*-lauroyl sarconisate is obtained, a product which is used as a detergent. If long-chain olefins

are amidocarbonylated in the presence of acetamide, long chain α-acetamido acids are obtained, which are also of interest as detergents:

Selectivities of up to 95 % can be achieved and the stability of the cobalt carbonyl can be improved by ligands such as 1,3-bis(diphenylphosphino)propane. Further potential applications are the synthesis of intermediates for sweeteners such as aspartame, food additives such as glutamic acid, and of chelating agents such as the polyamido acids. An advantage of this synthesis is that it can substitute HCN or halogenated intermediates. Palladium catalysts have also been investigated for this reaction. They offer a higher catalyst activity by a factor of about 100 over cobalt and a turnover number of 60 000 has been achieved in the case of *N*-acetylleucine. Palladium catalysts also allow the synthesis of hydantoins from substituted ureas as the amide equivalent and of arylglycines from substituted benzaldehydes [153].

1. Introduction

Aliphatic carboxylic acids have the general formula

where R is H or a straight-chain or branched-chain alkyl group. The first three members of this homologous series, formic, acetic, and propionic acid, are exceptionally important and are discussed in separate articles. Similarly, acids containing 12 or more carbon atoms are described separately under → Fatty Acids. The unsaturated acids acrylic, methacrylic, crotonic, and sorbic acid are also treated separately, as are chloroacetic and oxo- and hydroxycarboxylic acids.

The continuing scientific importance of the $C_4 - C_{11}$ carboxylic acids arises from their functions in the metabolism of plants and animals (see Chap. 4). The great commercial value of these acids, and particularly of their salts and esters, is based on their synthetic utility (see Chap. 9).

Numerous aliphatic carboxylic acids were first obtained from natural sources in the 19th century along with many other natural products. However, these natural sources, which usually yielded straight-chain acids containing an even number of carbon atoms, have since been replaced by large-scale synthetic operations (see Chaps. 5 and 10).

2. Physical Properties

The properties of the important saturated and unsaturated aliphatic monocarboxylic acids are listed in Table 1 which also includes typical values of commercial mixtures.

Carboxylic acids are usually colorless. The *n*- and isoalkane carboxylic acids up to C_9 are liquids, as are the highly branched acids up to C_{13}, except for pivalic acid.

The volatility and characteristic odor of carboxylic acids decrease with increasing molecular mass. The odors of butyric and valeric acids are generally perceived as unpleasant; higher homologues and commercial mixtures have fainter smells. The lower saturated carboxylic acids are miscible with water; solubility decreases rapidly from C_5 up. Higher carboxylic acids are almost insoluble in water but miscible with most organic solvents. They are partially associated in polar solvents. In aqueous solution, carboxylic acids behave as weak acids; their strength changes only slightly with increasing molecular mass. The dissociation constants are between 1 and 2×10^{-5}.

3. Chemical Properties

The carboxyl group is the target of most reactions [1], [2] and is hardly affected by the carbon chain. However, the carboxyl group activates the α-position, which is also an important reaction site.

Alkali metal salts of carboxylic acids are readily obtained by neutralization. They undergo only limited hydrolysis in aqueous solutions, which are nearly neutral. Salts of the lower carboxylic acids are soluble in water. Alkali metal salts are poorly soluble in organic solvents; heavy metal salts, on the other hand, are soluble in organic solvents and can be prepared from the alkali metal salts. Zinc salts can be produced by treating the metal with the acids at high temperature. Esters are formed by an acid-catalyzed reaction between carboxylic acids and alcohols or olefins. Polyols such as glycerol or cellulose may react completely or partially. In the second case mixtures of esters are formed. Because of steric hindrance, esterification becomes more difficult with increasing chain length or branching. Addition of carboxylic acids to acetylene gives vinyl esters capable of polymerization.

In the presence of halogenating compounds, e.g., thionyl halides, phosphorus halides, or phosphorus oxyhalides, the highly reactive, unstable acyl halides, a valuable class of synthetic intermediates, are formed. With ammonia or amines the acyl halides give amides, with alcohols esters, and with carboxylic acids anhydrides. These derivatives can also be obtained directly from the carboxylic acids.

Ketenes are obtained from the lower carboxylic acids or anhydrides by pyrolysis; the higher homologues are obtained by dehydrochlorination of the acyl chlorides.

In the presence of such catalysts as aluminum oxide, thorium oxide, or boron phosphate, monocarboxylic acids give ketones with loss of carbon dioxide and water:

$$2\ \mathrm{RCOOH} \xrightarrow{\text{Cat.}} \mathrm{R\underset{\underset{O}{\|}}{C}R} + \mathrm{CO_2} + \mathrm{H_2O}$$

Reactions involving an unsubstituted carbon chain usually require more severe conditions than reactions of the carboxyl group. Halogenation often produces mixtures but sites of chain-branching are attacked preferentially. For example, isobutyric acid gives mostly the α-chloro derivative. Nitric acid oxidation gives dicarboxylic acids with some chain degradation. Permanganate oxidation produces oxalic and acetic acids under alkaline and acidic conditions, respectively.

4. Natural Sources

Low concentrations of aliphatic acids are widely distributed in nature. The free acids occur in plants, e.g., formic acid in stinging nettles and pine needles. Butyric acid is found in vegetable oils and in animal fluids, such as sweat, tissue fluids, and milk fat. Isobutyric acid is found in carob bean, isovaleric acid in valerian root. Other acids occur in fruit.

In animals, free carboxylic acids are important metabolites in the breakdown of carbohydrates, fats, and proteins, in the so-called tricarboxylic acid cycle (citric acid cycle). Nearly all naturally occurring acids have an even num-

ber of carbon atoms, which suggests a common synthetic pathway utilizing two-carbon units.

Esters occur more frequently than free acids and are important constituents of perfumes and essential oils. Esters of glycerol with various aliphatic acids are found in animals and plants. However, natural sources of carboxylic acids up to C_{11} have little or no commercial importance, because they frequently occur in low concentration only and their isolation is difficult.

5. Production [1], [2]

The four important commercial methods of production are (1) aldehyde oxidation, (2) carboxylation of olefins (Koch synthesis), (3) paraffin oxidation, and (4) alkali fusion of alcohols. The hydrolysis of natural oils such as castor and soybean oil for heptanoic acid and undecanoic acid is less important.

At present, biochemical processes are of limited importance. Butyric acid is produced from sugar or starch by *Bacillus butylicus,* from methanol by *Butyribacterium methylotrophicum* [3], or from CO or CO_2 by *Eubacterium limosum* [4]. However, commercial interest in biochemical methods may increase in the near future.

Similarly, catalytic air oxidation of alcohols has not yet attracted the interest of industry. Examples are the oxidation of 3-methyl-1-butanol to isovaleric acid (82 % yield), of 2-ethyl-1-hexanol to 2-ethylhexanoic acid (84 % yield), and of 1-decanol to *n*-decanoic acid (89 % yield) [5].

Although hydroformylation of methanol gives excellent yields of acetic acid, higher alcohols give much poorer yields. Thus, 1-heptanol gave only a 66 % yield of 1-octanoic acid with a ruthenium catalyst [6]. Homologation with palladium complexes and iodides gave similar results [7] (→ Carbonylation).

Carboxylic acids are also obtained by careful oxidation at low temperature and low concentration with one of the following agents: ozone, nitric acid, chlorine, chromic acid, permanganate, or periodate. However, these reagents are used especially when other functional groups are present in the molecule, and the reactions are largely limited to laboratory operations.

High-pressure hydrocarboxylation can be used for the conversion of propylene into isobutyric acid (main product) and *n*-butyric acid in the presence of a palladium catalyst [8].

5.1. Saturated Monocarboxylic Acids

5.1.1. Aldehyde Oxidation

The principal method for the commercial production of $C_4 - C_{13}$ carboxylic acids is catalytic oxidation of the corresponding aldehydes:

$$RCHO + 1/2\ O_2 \longrightarrow RCOOH$$

This highly exothermic reaction liberates between 250 and 300 kJ/mol.

The starting materials are produced catalytically from olefins with CO and H_2 by the oxo process, which was developed in 1938 by Ruhrchemie AG, Oberhausen, in Germany [9] (→ Oxo Synthesis). Virtually any olefin can be used in this process, giving access to a wide range of aldehydes oxidizable to the corresponding carboxylic acids. Other aldehydes can be produced via aldol condensation, increasing the range of accessible carboxylic acids. Because of the complex nature of the olefinic raw materials, the higher carboxylic acids obtained (C_8 and higher) are usually mixtures of branched-chain products.

The aldehydes are oxidized by air or oxygen with or without a catalyst. Liquid-phase oxidation without solvent is preferred, although vapor-phase oxidation is feasible. Side reactions are suppressed when the temperature is only slightly increased. Thorough dispersion of oxygen in the liquid medium is important, especially in the absence of catalysts [10].

Effective catalysts are the salts of metals that appear in more than one oxidation state, e.g., silver, cerium, cobalt, chromium, copper, iron, manganese, molybdenum, nickel, and vanadium. For liquid-phase oxidation, these metals are used as soaps or naphthenates, or in the form of complexes, such as $K_3\,[Fe(CN)_5 \cdot H_2O]$ [11]. In vapor-phase oxidation, oxides are predominantly used, supported on silicates, diatomaceous earth, silica gel, quartz, or alumina. Catalysts containing manganese or copper or both can be reclaimed by precipitation with oxalic acid [12].

Where side reactions or decomposition may occur during oxidation, as in the case of 2-ethylhexanal, selectivity is improved by using the alkali or alkaline earth salts of weak acids [13].

The following conditions are optimal for the oxidation of isobutyraldehyde to isobutyric acid: (1) temperature 50 °C, residence time ca. 3 h, and 0.02 g catalyst per mole of isobutyraldehyde; (2) temperature 60 °C, residence time 50 min, and 0.06 g catalyst per mole of isobutyraldehyde. The catalyst in each case is a mixture of cobalt, manganese, and copper acetates (1 : 1 : 1); oxygen is passed through in slight excess. Conversion is 100 %, selectivity 90 % [14]. A low pressure gives isobutyric acid with more desirable properties [15].

Peroxycarboxylic acids appear to be intermediates in both uncatalyzed and catalyzed liquid-phase oxidation:

Aldehyde oxidation is usually carried out in stainless steel, but glass and enamelled vessels are also used (see Chap. 8).

5.1.2. Carboxylation of Olefins, Koch Process

Carboxylic acids are produced directly from olefins at high pressure as follows [16], [17] (→ Carbonylation):

This eliminates the oxo-aldehyde step.

Reppe carbonylation, limited commercially to the conversion of ethylene into propionic acid, is carried out in the presence of metal carbonyls. The Koch carbonylation employs proton catalysis and is usually accompanied by double bond and structure isomerization to give branched, predominantly tertiary acids [18]. Mixtures are mainly produced; the proportion of tertiary acids depends on reaction conditions. For example, at 80 °C, a CO pressure of 10 MPa (100 bar), and prolonged residence time, all butene isomers are converted mainly into pivalic acid (trimethylacetic acid).

In addition to olefins (except for ethylene) and cycloalkenes, alcohols and alkyl halides may also serve as starting materials. Strong mineral acids, such as H_2SO_4, HF, or H_3PO_4, alone or in combination with BF_3, or SbF_5, serve as catalysts; anhydrous conditions are required to give high yields.

The commercial process employs two stages. In the first stage, using a stirred vessel cascade, CO is added to the olefin in the presence of the catalyst, at 20 – 80 °C and 5 – 10 MPa (50 – 100 bar); the preferred catalyst is $H_3PO_4 \cdot BF_3$. In the second stage water is added. The reaction mixture separates into a product phase containing the carboxylic acid and into a second phase that contains the catalyst which can then be recycled. The crude acids are washed with sulfuric acid, hydrogen carbonate, and citric acid, and are then distilled. Tertiary carboxylic acids are formed at high conversion rates with 85 – 95 % selectivity. Carboxylic acids derived from the dimerized olefins are produced as byproducts. The use of alcohol instead of water in the second stage produces esters.

The Koch process is employed commercially by Shell, Exxon (Enjay) [19], [20], Kuhlmann, and Du Pont. In addition to isobutene which gives pivalic acid, diisobutene and $C_6 - C_8$ and $C_8 - C_{10}$ cuts are also used as raw materials. On the basis of these olefins an economical and widespread production has been developed. The products are marketed as Versatic Acids (Shell), Neo Acids (Exxon), and CeKanoic Acids (Kuhlmann). The Koch synthesis is conducted in Hastelloy-C or lined pressure vessels (see Chap. 8).

5.1.3. Oxidation of Alkanes

The oxidation of paraffin waxes, polyethylenes, or polypropylenes with oxygen or air produces mixtures of straight- and branched-chain monocarboxylic acids ranging from formic acid to acids with the same number of carbon atoms as the starting material.

The reaction takes place above 100 °C in a melt or an aqueous suspension. The pressure is slightly above atmospheric; a catalyst may be

employed. The heat of reaction must be effectively removed.

This method is not selective; it produces large amounts of CO_2 and modest yields of products which are inseparable mixtures of acids, but can be used as such.

In this way, Rhône-Poulenc produces butyric acid in large amounts as a byproduct of naphtha oxidation.

A variant of alkane oxidation is the vapor-phase cracking of high-molecular alkanes in the presence of CO_2 at 500 – 700 °C with very short residence times [21], [22].

5.1.4. Alkali Fusion of Alcohols

This method is still used occasionally to produce carboxylic acids of intermediate chain length in good yields:

$$RCH_2OH + NaOH \longrightarrow RCOONa + 2\,H_2$$

Oxo alcohols from C_8 are possible starting products; their carbon skeleton is preserved. The process is carried out with NaOH or NaOH–KOH mixtures at a temperature of 250 – 300 °C (ca. 2 MPa) in stainless steel or copper pressure vessels [23]; [24].

5.2. Unsaturated Monocarboxylic Acids

Acrylic, methacrylic, crotonic, and sorbic acids are discussed in separate articles; other unsaturated carboxylic acids with less than 12 carbon atoms are not of commercial importance. However, the following two processes are employed on a small scale:

Dimethylacrylic acid is obtained in excellent yields from acetone and ketene:

Homologous ketones and ketenes react similarly.

Propiolic acid, acetylenecarboxylic acid, H−C≡C−COOH, is produced by oxidizing propargyl alcohol at a lead anode in the presence of sulfuric acid [25]. The temperature is kept below 20 °C; the electrolytes are separated from each other by membranes. 2-Butyne-1,4-diol gives acetylenedicarboxylic acid, HOOC−C≡C−COOH.

6. Environmental Protection

The strong and unpleasant odors of many of these acids call for special protective measures. For example, the odor threshold of *n*-butyric acid is 8.8×10^{-13} g/L. These acids are readily removed from waste gas emanating from plants and storage tanks by an alkaline wash. Mixtures with aldehydes, e.g., from oxo syntheses, are removed by burning in a waste-gas flare or in a muffle furnace.

The degrees of degradation and BOD_5 values in a biological treatment plant have been determined for sodium carboxylates in wastewater using the Test for Biological Degradation from OECD-Guidelines 302 B (see Table 2).

Table 2. Biodegradation of sodium carboxylates [a]

Acid	Degradation, in 10 – 15 days, %	BOD_5 [b]
Isobutyric	>95	1160
Isovaleric	>95	1140
2,3-Dimethylbutyric	>96	<10
2,2-Dimethylpentanoic	>95	<10
Isoheptanoic	95	1350
Isooctanoic [c]	96	650
Isononanoic	95	125
Isodecanoic	79	690
Tridecanoic	48	40
Dimethylacrylic	96	590

[a] Straight-chain monocarboxylates are easily degraded.
[b] Biochemical oxygen demand: mg O_2 per liter of waste-water; sum over 5 days.
[c] Mixture.

7. Quality Specifications and Analysis

Manufacturers' specifications for the European market are given in Table 3. Specifications for the world market are similar.

Titration with aqueous alkali is satisfactory for many purposes; the preferred indicators are bromobenzene green, bromophenol blue, or phenolphthalein. The less soluble higher acids are titrated in aqueous methanol or ethanol or with methanolic KOH. Lauric acid is a suitable calibration standard.

Table 3. Manufacturers' specifications for commercial aliphatic carboxylic acids

Acid	Content, wt % min.	Boiling range, 2 – 97 % at 101.3 kPa, °C	Density at 20 °C, g/cm^3	Refractive index n_D at 20 °C	Hazen Color Index, max. APHA	Water content, wt %, max.	Freezing or melting temperature, °C
n-Butyric	99.5	161 – 164	0.956 – 0.959	1.398 – 1.399	15	0.1	− 5
n-Valeric	99	184 – 188	0.937 – 0.940	1.408 – 1.409	20	0.1	−32
Isobutyric	99.4	151 – 155	0.946 – 0.950	1.393 – 1.394	15	0.1	−46
2-Methylbutyric	99.3	176	0.935	1.406	5	0.05	<−60
Isovaleric	98.5	175 – 177	0.925 – 0.927	1.403 – 1.404	15	0.2	ca. −26
2-Methylpentanoic	99	196	0.921	1.414	ca. 10	0.1	<−60
2-Ethylbutyric	99	192 – 196	0.921 – 0.924	1.413 – 1.414	15	0.2	−13
2-Ethylhexanoic	99.2	226 – 230	0.905 – 0.907	1.425 – 1.426	15	0.1	−60
Di-*n*-propylacetic	99.5	225 – 229	0.903 – 0.906	1.424 – 1.426	20	0.1	<−60
Isooctanoic ∗	99	225 – 238	0.913 – 0.917	1.428 – 1.431	20	0.1	<−60
Isononanoic ∗∗	99	233 – 245	0.897 – 0.901	1.429 – 1.431	20	0.1	<−60
Isodecanoic ∗	99	252 – 269	0.903 – 0.906	1.436 – 1.438	35	0.1	ca. −60
Isotridecanoic ∗	99		0.897 – 0.902	1.446 – 1.447	50	0.2	−46

∗ Mixture of isomers.
∗∗ Ca. 90 % 3,5,5-trimethylhexanoic acid.

Titration against a glass–calomel electrode also gives excellent results; a graph is used to calculate the acid concentration [26].

Mixtures can be analyzed with great precision by gas chromatography; higher acids are first converted into methyl esters. The stationary phase in the GC column may contain Carbowax 20M impregnated with terephthalic acid, or polyglycol esters such as type Sp 1200/H_3PO_4 (10 : 4 %). Helium or nitrogen is used as carrier gas.

Paper or thin-layer chromatography [27] and spectrophotometric methods [28] are also used.

8. Storage and Transportation

Most aliphatic carboxylic acids are corrosive and flammable; flammability properties are given in Table 4. Carboxylic acids must be stored and transported in corrosion-resistant containers. Stainless steel and aluminum are used, but aluminum is subject to attack at certain concentrations. Polyethylene-lined metal drums are suitable for the lower acids. For acids with more than six carbon atoms, drums coated with acid-resistant paint are used. The higher-melting acids, e.g., lauric acid, are transported in paper bags or fiber drums lined with polyethylene.

Table 4. Flammability properties of aliphatic carboxylic acids [a]

Acid	Flash point, °C (Abel-Pensky)	Ignition temperature, °C
n-Butyric	69	425
Isobutyric	59	420
n-Valeric	86	360
2-Methylbutyric [b]	77	495
3-Methylbutyric	74	440
2-Methylpentanoic	95	390
2-Ethylbutyric	87	345
2-Ethylhexanoic	114	320
2-*n*-Propylpentanoic	113	350
Isooctanoic [c]	118	440

[b] Ignition group G 1.
[c] Mixture of isomers.

9. Uses

Carboxylic acids may undergo many reactions and have a wide variety of applications [1].

Esters, particularly those of branched-chain acids, are widely employed as solvents. The lower esters are good solvents for nitrocellulose and other cellulose derivatives. Esters have low polarity and low water solubility. Large quan-

tities are used in perfumes [29]. They are the principal constituents of many essential oils. Because of their flavor and aroma, the lower esters are also known as fruit ethers.

Carboxylic acids are incorporated into plastics. Much of the acids produced from oxo-process aldehydes is used for the manufacture of alkyd resins. Long-chain carboxylic acid groups increase solubility in organic solvents, compatibility with softeners, suppleness, and toughness.

Copper salts of branched-chain acids are important preservatives. Copper and zinc salts are used as fungicides and insecticides. Cobalt, lead, manganese, and iron salts are employed as drying agents for paints and printing inks. Because of their good miscibility with solvents and binding agents oxo-process acids give drying agents with a higher metal content than that afforded by naphthenic acids.

Carboxylic acids are also used as intermediates for textile chemicals, dyes, drugs, plastics, and agricultural chemicals. Amides and other derivatives serve as corrosion inhibitors, detergents, flotation aids, and oil additives.

10. Specific Aliphatic Carboxylic Acids

10.1. Butyric Acids

n-Butyric acid is produced commercially by the liquid-phase oxidation of *n*-butyraldehyde with oxygen. In the continuous process conversion is 97 – 98 % and selectivity over 95 %. The product, a colorless mobile liquid, is purified by vacuum distillation. Its penetrating and persistent odor is pungent when concentrated, and rancid or sweaty when diluted. The acid is miscible at room temperature with water and most organic solvents. It is steam-volatile and forms an azeotrope with water (18.5 wt % of butyric acid) boiling at 99.4 °C. Butyric acid esters are used to manufacture lacquers, plastics, and perfumes. Cellulose butyrates are more soluble in organic solvents than cellulose acetate and more miscible with resins and softeners.

Cellulose acetate butyrate is used for plastics with good physical stability and melting behavior. These plastics are suitable for molding. Being highly resistant to humidity, heat, and light, cellulose acetate butyrate gives excellent cable coatings and fishing tackle (→ Cellulose Esters).

Glycerol butyrates and *N*-arylbutyramides serve as softeners in cellulose-based plastics. The esters of monoalcohols have a pleasant, fruity aroma and are used in perfumes.

Isobutyric acid (2-methylpropanoic acid) is produced almost exclusively by the oxidation of isobutyraldehyde, a cheap byproduct of the hydroformylation of propene. This oxidation is less selective than that of *n*-butyraldehyde. Isobutyric acid is a colorless, clear liquid with a characteristically pungent and unpleasant odor. Above 26 °C, isobutyric acid and water are completely miscible. At 20 °C the aqueous phase contains 22 wt % of isobutyric acid and the organic phase contains 55 wt % of water. Miscibility with most organic solvents is also good. The water–isobutyric acid azeotrope boils at 99.3 °C and contains 21 wt % of the acid.

Isobutyric acid is valuable as a polar solvent [30], as starting material for diisopropyl ketone [31], and as a herbicide [32]. Its salts are used as textile chemicals, tanning compounds, stabilizers, catalysts, and preservatives. The esters are used in perfumes, as solvents, and as special oils for aircraft turbines.

10.2. Valeric Acids

n-Valeric acid, *n*-pentanoic acid, is a clear liquid with a characteristic, unpleasant odor. It is produced by the oxidation of *n*-valeraldehyde with oxygen. Its miscibility with water is limited, but it is fully miscible with common organic solvents.

Many esters of *n*-valeric acid with the lower alcohols are used as solvents and in aromas and perfumes [33]; esters with higher alcohols are used as softeners [34]. The ethyl ester is a lubricant. The sodium and calcium salts and some derivatives are used as rodenticides or fungicides.

2-Methylbutyric acid is produced by oxidation of 2-methylbutanal. Its properties and uses resemble those of *n*-valeric acid.

Valeric acid. A mixture of *n*-valeric acid (65 %) and 2-methylbutyric acid (35 %) is obtained directly by oxidation of the valeraldehyde mixture produced by oxo synthesis from

n-butene. In its properties and uses it resembles *n*-valeric acid.

Isovaleric acid, 3-methylbutyric acid, is a clear liquid with a highly unpleasant odor. It is produced by oxidation of isovaleraldehyde, which is obtained from isobutene. It is sparingly soluble in water (ca. 2.5 %), but readily soluble in organic solvents. It is used to make fungicides, rodenticides, and sedatives, narcotics, and other drugs. The esters are used as solvents and softeners and in perfumes [29]. The ammonium salts in particular are known for their rodenticidal properties.

10.3. Octanoic Acids

n-Octanoic acid, caprylic acid, is produced from oxo aldehydes. It is used in hydraulic fluids, machining oils, flotation agents [35], and as a wood preservative [36].

Isooctanoic acid is produced by the oxidation of the corresponding aldehyde. The commercial product is a mixture of methyl-branched isomers. It is a clear colorless liquid with a weak odor, practically insoluble in water, but miscible with most organic solvents. It is used in alkyd resins for high-quality lacquers.

Esters of isooctanoic acid, especially those of glycols and polyglycols, and amides are used as plasticizers for PVC polymers. Esters with glycols are widely employed in lubricating oils.

The lithium, magnesium, and aluminum salts are used in lubricants and the heavy metal salts in binding agents. Other derivatives are used as corrosion inhibitors, detergents, flotation aids, oil additives, hydraulic fluids, and preservatives. Uses are similar to those of 2-ethylhexanoic acid.

10.4. 2-Ethylhexanoic Acid

2-Ethylhexanoic acid is produced by oxidation of 2-ethyl-1-hexanol or 2-ethylhexanal; the latter is obtained in 95 % yield by hydrogenation of 2-ethyl-2-hexenal, which is itself formed by the aldol condensation of *n*-butyraldehyde (→ Aldehydes, Aliphatic and Araliphatic). In this way propene becomes the source of 2-ethylhexanoic acid. Its accessibility and utility have made it one of the acids with the highest production capacities worldwide. It is of particular importance in the production of alkyd resins used for baking enamels because of their exceptional stability even at temperatures over 200 °C and their good weathering and aging stability.

Esters of 2-ethylhexanoic acid, especially those of diglycols, triglycols, and polyethylene glycol, are used as plasticizers and stabilizers for PVC polymers. Peroxides of 2-ethylhexanoic acid are catalysts in the production of low-density polyethylene.

The lead, cobalt, manganese, and zinc salts are soluble in hydrocarbons. Such solutions serve as drying agents for lacquers and enamels. The iron, nickel, and cobalt salts are used as stabilizers for silicones. The copper salt is a fungicide for marine and other applications.

The acid and its derivatives are also used in the manufacture of lubricants, detergents, flotation aids, and corrosion inhibitors, as catalysts for polyurethane foaming, for solvent extraction [37], and for dye granulation [38]. Versatic Acid 10 (Shell) is used similarly.

10.5. Nonanoic Acids

Pelargonic acid , *n*-nonanoic acid, is manufactured via the oxo process and from oleic acid in 96 % yield by double-bond cleavage with ozone, nitric acid [39], or chlorine [40].

Like isononanoic acid, it is used in the manufacture of lubricating oils, peroxides, perfumes, and catalysts for alkyd resins.

Isononanoic acid, produced by the oxidation of isononyl aldehyde, is a mixture of isomers, containing more than 90 % 3,5,5-trimethylhexanoic acid. The starting aldehyde is obtained by the hydroformylation of diisobutene. The acid is also obtained directly from diisobutene by the Koch synthesis in 83 – 86 % sulfuric acid at 20 °C and a CO pressure of 7 MPa (70 bar); the main product in this case is 2,2,4,4-tetramethylpentanoic acid.

Isononanoic acid is a clear, colorless liquid with a weak odor. It is almost insoluble in water, but absorbs about 1.6 % water at 20 °C. It is miscible with most organic solvents. It is used for the same applications as isooctanoic acid; its higher molecular mass is sometimes advantageous.

Isononanoic acid is used in alkyd resins for high-quality lacquers and coatings. As such, it

provides excellent mechanical properties, surface hardness, color stability up to 200 – 230 °C, excellent gloss, and no yellowing.

Isononanoic acid esters are good stabilizers. Glycol and polyglycol esters are used in hydraulic fluids; they are also suited as lubricants under extreme conditions, e.g., in jet aircrafts, because of their good viscosity/temperature coefficient over a wide range. Metal salts find application in lubricating greases and as oxidative drying agents for lacquers. The copper salt is a fungicide. Derivatives are used as corrosion inhibitors, detergents [41], flotation aids, and catalysts.

Isononanoic acid can be replaced by Versatic Acid 10 (Shell) and Cardura E (Shell) or by CeKanoic 9 (Kuhlmann).

Table 5. Trade names and manufacturers of carboxylic acids

Chemical name	Trade name	Manufacturer
Valeric acid mixture	Neopentanoic Acid 5	Exxon
Valeric acid mixture	Versatic Acid 5	Shell
Octanoic-, nonanoic-, and decanoic acid mixtures with isomers	Neodecanoic Acid 10	Exxon
	Versatic Acid 10	Shell
	Cardura E	Shell
Isooctanoic acid mixture	CeKanoic 8	Kuhlmann
Isononanoic acid mixture	CeKanoic 9	Kuhlmann
Isodecanoic acid mixture	CeKanoic 10	Kuhlmann
Nonanoic and undecanoic acid mixture	Versatic Acid 911	Shell

10.6. Isodecanoic Acid

Isodecanoic acid is produced by oxidizing the mixture of aldehydes obtained from tripropylene in the oxo process. It is used in drying agents, PVC stabilizers, and alkyd resins; the copper salt is a wood preservative [42]. Isodecanoic acid may be replaced by versatic acid 10 or neodecanoic acid.

10.7. Pivalic Acid

Pivalic acid, trimethylacetic acid, is produced from isobutene in ca. 95 % yield by the Koch synthesis at 40 – 60 °C at a CO pressure of 5 MPa (50 bar) and with HF as catalyst [43–45]. Isobutanol or *tert*-butyl alcohol also serve as starting material [46].

Chain branching confers unusual properties on pivalic acid. The esters are very resistant to hydrolysis; some are heat-resistant lubricants. The poly(vinyl)esters form highly reflective lacquers with good weathering properties. The acid is used in cosmetics and for analgesic, anti-inflammatory, and antispasmodic preparations. It can replace *n*-valeric acid in various applications.

10.8. Versatic Acids and Neo Acids

These two acids, designated by trade mark (see Chap. 11), are prototypes of a group of highly branched carboxylic acids, mostly of 5 – 13 carbon atoms. They are produced on a large scale by the Koch synthesis; each product is a mixture of branched isomers and acids with varying numbers of carbon atoms. The name (e.g., Neononanoic Acid) or a numerical suffix (e.g., Versatic Acid 10) ordinarily refers to the number of carbon atoms in the constituent of highest molecular mass.

All these acids are liquids with a weak odor, miscible with organic solvents, but only slightly soluble in water. They can be vacuum distilled and are stable to about 250 °C. The exceptional thermal stability and the resistance to oxidation and hydrolysis are caused by the bulky tertiary alkyl groups of these acids or esters. They are therefore suitable as components of synthetic lubricants or hydraulic fluids. The vinyl esters are used as comonomers and plasticizers in vinyl chloride resins. The glycidyl esters are alkyd resin modifiers. The metal salts are drying agents.

10.9. Propiolic Acid

Propiolic acid, acetylenecarboxylic acid, is produced electrochemically from propargyl alcohol and used in agriculture and in the control of nematodes [47].

11. Trade Names, Economic Aspects

Most carboxylic acids are sold under their chemical names; exceptions are listed in Table 5. The 1980 consumption figures and 1983/84 production capacities for the most important products with a known capacity of more than 50 t/a are given in Table 6 [48].

Table 6. Economic aspects of aliphatic monocarboxylic acids

	Manufacturers [a]; production capacities (1983/1984), t/a			1980 Consumption, t		
	Western Europe	USA	Japan	Western Europe	USA	Japan

12. Toxicology and Occupational Health

The saturated aliphatic carboxylic acids of 4 – 11 carbon atoms are not known as human poisons [49]; large doses are harmful when applied locally. The lower homologues are corrosive. With increasing chain length and decreasing water solubility, they become less irritating. They can be detected even in low concentrations by the pungent and sweaty odor of the lower homologues and the paraffinic odor of the higher ones. Inhalation of high concentrations can cause breathing difficulties and lung edema. Carboxylic acids are classified as dangerous substances; see also [50]. Chlorination increases acid strength and toxicity. Protective goggles and gloves must be worn when handling carboxylic acids to prevent contact with skin or clothing. If contact occurs, the affected

area should be liberally rinsed with water and the clothing changed. Chlorocarboxylic acids require special precautions.

The lethal doses LD_{50} for rats are given in Table 7. Neither MAK values nor TLVs have been established, indicating that harmful concentrations are not likely to arise in the workplace.

13. Derivatives

13.1. Acyl Halides

Only the acyl chlorides have commercial importance. They are obtained from carboxylic acids and their salts by halogenation with PCl_5, $POCl_3$, $SOCl_2$, SO_2Cl_2, or $COCl_2$. Alternatively, olefins are treated with hydrochloric acid and carbon monoxide at high pressure in the presence of palladium catalysts:

$$CH_2{=}CH_2 + CO + HCl \longrightarrow CH_3CH_2COCl$$

Vinylacetyl chloride [*1470-91-3*], $CH_2{=}CH{-}CH_2COCl$, can be produced from carbon monoxide and allyl chloride; acid bromides can be obtained by the same method.

Isobutyryl fluoride [*430-92-2*], $(CH_3)_2CHCOF$, can be prepared in 95 % yield from isopropyl fluoride [*420-26-8*], $(CH_3)_2CHF$, using CO and anhydrous HF at 0 – 80 °C and 1 – 5 MPa (10 – 50 bar) [52].

Acid chlorides have a pungent odor. They are thermally stable but easily hydrolyzed.

13.2. Anhydrides

Anhydrides of the lower carboxylic acids are mobile-to-oily liquids. Viscosity increases with molecular mass. The higher anhydrides are solids. From C_4 to C_7 the unpleasant odor resembles that of the carboxylic acids; the higher homologues possess little or no odor. In water, the lower members hydrolyze readily to the corresponding carboxylic acid; the higher members require prolonged heating.

Anhydrides can be obtained by the reaction of acyl chlorides with carboxylic acids or their salts or directly by oxidation of aldehydes with oxygen. An important synthesis of the higher homologues makes use of mixed anhydrides with acetic acid. These are formed from the acid by reaction with acetic anhydride or ketene. They react with a second mole of acid to give the symmetrical anhydride and one mole of acetic acid that is removed by a distillation; the removal may be accelerated by passing a stream of inert gas through the mixture. The process may be carried out in one step; yields are over 90 %:

$$RCOOH + CH_2{=}C{=}O \longrightarrow RCOOCOCH_3$$

$$RCOOCOCH_3 + RCOOH \longrightarrow (RCO)_2O + CH_3COOH$$

Another method is the addition of acetic anhydride to α-olefins using di-*tert*-butyl peroxide as the catalyst. For the reaction of olefins with CO and water to produce anhydrides, see → Carbonylation. The higher anhydrides are used mainly in the acylation of cellulose, e.g., propionate and butyrate (→ Cellulose Esters).

Table 7. Toxicity of aliphatic carboxylic acids

Acid	LD_{50} [a], mg/kg
n-Butyric	2940
n-Valeric	1120
Isobutyric	280
Isovaleric	2000
Pivalic	900
2-Methylpentanoic	2040
n-Hexanoic	3000
2-Ethylbutyric	2200
2-Ethylhexanoic	3000
Di-*n*-propylacetic [b]	670
n-Nonanoic	3200
Isooctanoic [c]	1.41
Isononanoic [d]	3135
n-Decanoic	129
Isodecanoic [c]	3.73
Dimethylacrylic	3650

[a] Rats, oral.
[b] 2-*n*-Propylpentanoic acid [51].
[c] Mixture of isomers.
[d] Ca. 90 % 3,5,5-trimethylhexanoic acid.

13.3. Lactams

Lactams are internal amides of aminocarboxylic acids; the lactams of 3-, 4-, and 5-aminocarboxylic acids are more stable than the acids themselves. They are produced by the reaction of ammonia with chlorocarboxylic acids, hydroxycarboxylic acids, or lactones. The principal industrial process is the Beckmann rearrangement of ketoximes, used to produce caprolactam and laurolactam (→ Caprolactam).

High yields of pyrrolidones and piperidones (five- and six-membered lactams, respectively) are obtained by the reaction of unsaturated amines with carbon monoxide in the presence of a cobalt carbonyl catalyst [53].

The most important reaction of lactams is polymerization to produce polyamide fibers (Nylon) and plastics.

The principal lactams of commercial importance are caprolactam (BASF, Du Pont, Toyo Rayon, Snia Viscosa, Union Carbide, Allied Chemical), pyrrolidone, and *N*-methylpyrrolidone (BASF); the last is used as a solvent and extractant, for example, for the removal of olefins and butadiene from crack gas mixtures (BASF process) or of aromatics from petroleum (Lurgi Arosolvan process). *N*-Vinylpyrrolidone polymers are used in cosmetics.

13.4. Halogenated Carboxylic Acids

Mono-, di-, and trichloroacetic acid are produced commercially on a large scale and are discussed in a separate article (→ Chloroacetic Acids). The higher chloro- and fluorocarboxylic acids are important as intermediates and agents for pest control.

Chlorocarboxylic acids are produced by liquid- and gas-phase chlorination at ca. 300 – 400 °C; mixtures usually result. Liquid-phase reaction is accelerated by UV light. Tertiary carbon atoms react preferentially, but chlorinating agents such as $POCl_3$, PCl_5, and SO_2Cl_2 favor α-substitution. In addition, chlorination of aldehydes in aqueous solution produces α-chloroisobutyric and other α-chloro acids [54]. Addition of HCl to α,β-unsaturated acids gives β-chloro acids. For example, a high yield of 3-chloropropionic acid [*107-94-8*] is produced from concentrated HCl and acrylic acid at 60 – 100 °C [55]. Halogen addition yields α,β-dihalopropionic acid.

The most important chlorinated aliphatic acid, 2,2-dichloropropionic acid [*75-99-0*] [56], can be made by chlorination of propionic acid, propionaldehyde, or propanol (→ Propionic Acid and Derivatives) [57]. It is a colorless liquid, *bp* 186 – 189 °C, d_4^{23} 1.389.

The sodium salt, CH_3CCl_2COONa, is known as the herbicide Dalapon [*127-20-8*] (Dow Chemical), a hygroscopic powder which decomposes at 166.5 °C and is soluble in water to the extent of 90 g/100 mL at 25 °C. The calcium and magnesium salts are also highly soluble in water. The oral toxicity (LD_{50}) of Dalapon in rats is 6600 – 9300 mg/kg. It is a soil herbicide and a selective, systemic leaf herbicide and is used against perennial grasses [58]. However, its importance in Europe is decreasing.

Less important products are 3-chlorobutanoic acid [*1951-12-8*] and 3-chloro-2,2-dimethylpropanoic acid [*13511-38-1*] (Kodak).

The Koch synthesis with unsaturated halohydrocarbons appears likely to become more important [59]. For example, chloropivalic acid [*13511-38-1*] can be obtained in ca. 70 % yield from methallyl chloride using a BF_3 catalyst.

The chlorine of chloroacetic acid and other α-chloro acids may be replaced, e.g., by amino groups. β-Chloro acids can be converted into unsaturated acids by eliminating HCl; γ- and δ-chloro acids yield lactones.

Fluorocarboxylic Acids. Short-chain perfluorocarboxylic acids are used as intermediates, and the longer-chain ones, from about C_6, in surfactants. These compounds are discussed in a separate article (→ Fluorine Compounds, Organic).

1. Introduction

The production of virtually all industrially important aromatic carboxylic acids involves either the partial oxidation of aromatic alkyl groups or the partial oxidative degradation of the aromatic ring with atmospheric oxygen. The oxidation of the methyl groups of xylene exemplifies the former case.

The partial oxidation of naphthalene is an example of the oxidation of the ring.

Such oxidizing agents as dichromate, permanganate, hypochlorite, chlorine, and nitric acid, which were used a few decades ago, have been replaced in almost all cases by atmospheric oxygen. The advantage of air oxidation is that only carbon dioxide and water are formed as the main byproducts. The progress made in modern oxidation techniques has gone hand in hand with the development of the synthesis of benzoic acid and of the two major products phthalic acid and terephthalic acid.

2. Physical and Chemical Properties

The physical properties of the most important aromatic carboxylic acids are given in Table 1. The monocarboxylic acids of benzene and naphthalene are, without exception, crystalline solids melting at temperatures above 100 °C. The melting points of the dicarboxylic and polycarboxylic acids are usually higher than those of the monocarboxylic acids. The acidity of benzoic acid (pK_a 4.17) and of the naphthoic acids (α: pK_a 3.7, β: pK_a 4.15) is a little greater than that of acetic acid (pK_a 4.74). The acidity is enhanced by electron-attracting substituents,

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a05_249

especially those in the ortho position. Hence, in aromatic polycarboxylic acids, the acidity of the first carboxyl group is increased stepwise by the addition of further carboxyl groups (phthalic acid: pK_a 3.00, pyromellitic acid: pK_a 1.92).

In general, the chemistry of the carboxyl group of aromatic carboxylic acids does not differ from that of the carboxyl group of aliphatic carboxylic acids. Both form salts, esters, anhydrides, acid amides, and acid halides (→ Carboxylic Acids, Aliphatic). For this reason, only the most important reactions and some special features are discussed in detail here.

The esterification and amidation reactions of bifunctional carboxylic acids that yield polyesters and polyamides are of considerable industrial importance. The most important polyester, poly(ethylene terephthalate), is prepared by a two-stage reaction. Terephthalic acid or dimethyl terephthalate reacts with ethylene glycol at 200 °C in the molten state to give diglycol terephthalate:

In the next stage, conducted under vacuum conditions at approximately 280 °C and in the presence of an antimony catalyst, polycondensation occurs which releases ethylene glycol.

Among the polyamides, the condensation polymers of terephthalic acid and *p*-phenylenediamine (Kevlar) and of isophthalic acid and *m*-phenylenediamine (Nomex) are of practical importance because they can be converted into flameproof, temperature-resistant fibers.

Aromatic polycarboxylic acids readily undergo cyclization to give anhydrides if a strainless five- or six-membered ring can be formed. The reaction is carried out by heating at low pressure or by boiling with acetic anhydride.

The five-membered cyclic anhydrides react readily with water, alcohol, or ammonia. They undergo only partial esterification with alcohols, but the product can be completely esterified at a higher temperature.

They react with ammonia or primary amines to form acid amides, which when heated form imides.

The acid amides or acid imides can be converted to the *o*-aminocarboxylic acids by a sodium hypochlorite – sodium hydroxide solution; e.g., phthalimide can be converted to anthranilic acid. This is an example of the Hofmann degradation.

The six-membered cyclic anhydrides, which have the structure of naphthalic anhydride, form readily and are resistant to hydrolysis. They react easily with ammonia or primary amines to give imides.

The reaction with *o*-phenylenediamine yields imidazoles. The alkaline salts of aromatic dicarboxylic acids can undergo carboxyl group rearrangements at high temperature to form thermodynamically more stable structures (Henkel reaction).

Table 1. Aromatic carboxylic acids

Acid	Common name	Empirical formula	M_r	Chemical structure	*mp*, °C	*bp*, °C	Solubility in 100 g water, g	
							at 25 °C	at 100 °C
Benzenecarboxylic acid [*65-85-0*]	benzoic acid	$C_7H_6O_2$	122.12		122.374	249	0.34	2.19 (75 °C)
2-Hydroxybenzenecarboxylic acid [*69-72-7*]	salicylic acid	$C_7H_6O_3$	138.12		162	sublimes at 135 °C (650 Pa) sublimes at 150 °C (1930 Pa)	0.22	2.2 (80 °C)
trans-3-Phenyl-2-propenoic acid [*621-82-9*]	*trans*-cinnamic acid	$C_9H_8O_2$	148.16		134	300 (101.3 kPa)	0.055

1,8-Naphthalenedicarboxylic acid [*518-05-8*]	naphthalic acid	$C_{12}H_8O_4$	216.20		forms anhydride > 60 °C		sparingly soluble	
2,6-Naphthalenedicarboxylic acid [*1141-38-4*]		$C_{12}H_8O_4$	216.20		> 340		soluble in aqueous ethanol	
1,4,5,8-Naphthalenetetracarboxylic acid [*128-97-2*]		$C_{14}H_8O_8$	304.22		forms dianhydride > 80 °C		moderately soluble	
3,4,9,10-Perylenetetracarboxylic acid [*81-32-3*]		$C_{24}H_{12}O_8$	428.36		forms dianhydride		very soluble	

The copper-catalyzed oxidative decarboxylation of benzoic acid to form phenol is of considerable commercial importance. In the process developed by Dow Chemical, a mixture of air and steam at 220 – 250 °C and ca. 200 kPa is passed into molten benzoic acid. The resultant phenol leaves the reactor as a vapor. A selectivity of approximately 85 % is achieved using a copper benzoate catalyst.

3. Production

3.1. Carboxylation with Carbon Dioxide

Specific carboxylic acids can be prepared by introducing a carboxyl group directly into the aromatic ring. This is usually carried out by reacting carbon dioxide with an aryl Grignard reagent or an aryl lithium compound. However, this reaction is of limited use.

In the Kolbe–Schmitt reaction, carbon dioxide at approximately 0.5 MPa (5 bar) reacts at 130 – 180 °C with the alkali salt of a phenol or naphthol to give a hydroxycarboxylic acid (→ Salicylic Acid, → Hydroxycarboxylic Acids, Aromatic).

3.2. Dicarboxylic Acids Formed by Rearrangement

Procedures involving carboxyl group rearrangements are known as the Henkel I and Henkel II procedures. They are named after the company that discovered them [1].

In the Henkel I procedure, the potassium salt of a dicarboxylic acid undergoes rearrangement to give its thermodynamically more stable form. For example, dipotassium phthalate is converted into dipotassium terephthalate by Zn–Cd-catalyzed rearrangement under carbon dioxide at 1.5 MPa (15 bar) and 430 – 440 °C [2].

The Henkel II procedure is based on the disproportionation of aromatic carboxylic acids. For example, potassium benzoate can be converted into dipotassium terephthalate and benzene with a 95 % selectivity by using the same reaction conditions as described above for the Henkel I procedure [3]. Although these methods have been applied by Teijin (Henkel I) and Mitsubishi Chemical (Henkel II) to produce terephthalic acid, they are used today only in the production of special carboxylic acids, e.g., 2,6-naphthalenedicarboxylic acid [*1141-38-4*].

3.3. Side-Chain Chlorination of Methylbenzenes

For the preparation of acid chlorides, the side-chain chlorination of methyl-substituted aromatic compounds is often highly advantageous [4]. Indeed, photochlorination of toluenes and xylenes at 80 – 140 °C in glass, lead, or nickel reactors forms trichloromethyl-substituted aromatic compounds. The reaction must be carried out with complete exclusion of any trace of iron. The product in turn reacts with one equivalent of water or carboxylic acid over an iron(III) chloride or zinc chloride catalyst to yield the acid chloride.

The acid chloride can be hydrolyzed with water to form the corresponding carboxylic acid.

3.4. Oxidation with Nitric Acid

The oxidation of methyl-substituted aromatic compounds to the corresponding carboxylic acids requires long heating (> 160 °C) with dilute nitric acid [5]. These conditions are chosen to reduce nitration. A supply of air at 3 – 4 MPa can lower the consumption of nitric acid. The reaction is catalyzed by ammonium vanadate. Even if the oxidation conditions are optimum, a marked nitration of the aromatic compound

occurs. This method was at one time very important, and is still used by AB Bofors Nobel Kemi to oxidize nitrotoluenes, chloronitrotoluenes, and chlorotoluenes.

3.5. Oxidation with Molecular Oxygen in the Vapor Phase

The vapor-phase air oxidation of alkyl-substituted aromatic compounds or of multinuclear aromatic compounds to form aromatic carboxylic acids (e.g., *o*-xylene or naphthalene to phthalic anhydride) proceeds at 350 – 500 °C over a vanadium pentoxide catalyst. The catalyst is usually modified with titanium dioxide or sodium sulfate and is supported on a silica gel or silicon carbide carrier [6], [7]. The oxidation can take place in a fixed-bed reactor or in a fluidized-bed reactor. In the former case, the catalyst is firmly held in place in a multitubular reactor with 10000 or more tubes of about 1.5 cm inner diameter. Large amounts of heat are generated by the reaction, necessitating the use of a eutectic molten salt for cooling the tubes. The hydrocarbon reactant and air are passed into the reactor as a gaseous mixture. This procedure is used by Chemische Fabrik von Heyden, Veba Chemie, Koppers, BASF, Monsanto, and Rhône-Poulenc, and is suitable for the oxidation of *o*-xylene (at 380 – 400 °C, molar yield 78 %), naphthalene (at 400 °C, molar yield approximately 80 %), acenaphthene, and durene.

In 1944, the oxidation procedure using a continuous fluidized-bed reactor was introduced on a large industrial scale in the United States. It was used by Badger–Sherwin-Williams for the production of phthalic anhydride from naphthalene (see chapter 1). In this process liquid naphthalene is injected into the fluidized solid catalyst at 350 – 380 °C, using preheated air to maintain the flow. The main advantages of this technique are better control of the reaction heat and minimization of flammability problems. The yields obtained by it are lower than those in the fixed-bed process, especially when the starting material is *o*-xylene. The Badger Company, United Coke–Foster Wheeler, and ICI use the fluidized-bed reactor for the oxidation of naphthalene.

The gases leaving the reactor are passed through switch condensers where the product is almost quantitatively deposited on the cooled tubes. Hot oil is in turn passed through the tubes, and the product is melted off. The exhaust gas must be scrubbed before being discharged into the atmosphere. The vapor-phase oxidation gives molar yields of up to 80 % and is suitable for the production of maleic anhydride, benzoic acid, phthalic anhydride, naphthalic anhydride, and pyromellitic anhydride.

3.6. Oxidation with Molecular Oxygen in the Liquid Phase

Many carboxylic acids are destroyed by the high temperatures required in the gas-phase oxidation technique or they are just not sufficiently volatile. These acids can be effectively produced by catalytic oxidation in the liquid phase. The starting materials are alkyl-substituted aromatic compounds, and the reaction is carried out either in a column or in a pressure reactor with effective mixing. Although acetic acid is generally the most useful solvent, oxidation can also occur in the absence of solvent. Cobalt or manganese salts are commonly used as catalysts.

3.6.1. Solvent-Free Oxidation

A process developed by Snia Viscosa involves the oxidation of toluene to benzoic acid at 165 °C and 1 MPa (10 bar) and uses cobalt carboxylates as catalysts. A 20 – 30 % conversion and a selectivity of 90 % are achieved [8–10].

The Dynamit Nobel–Hercules procedure is used to make dimethyl terephthalate (DMT). This joint oxidation of *p*-xylene and the methyl ester of toluic acid at 150 – 170 °C and 400 – 800 kPa (4 – 8 bar) yields toluic acid and the monomethyl ester of terephthalic acid. This mixture is converted by pressure esterification with methanol at 200 – 250 °C to toluic acid methyl ester and DMT. The latter is isolated by distillation and recrystallized from methanol. The toluic acid methyl ester is then returned to the oxidation reactor along with fresh xylene [11].

3.6.2. Oxidation in Acetic Acid

Oxidation without addition of a solvent is in many ways disadvantageous because the resulting carboxylic acids have high melting points, and, therefore, only limited conversion rates can be attained. However, 100 % conversion is possible when working in acetic acid. The resultant carboxylic acids usually precipitate as crystals, e.g., terephthalic acid and *p*-nitrobenzoic acid.

The main catalysts are soluble cobalt and manganese carboxylates. However, only in a few cases do these metal ions alone give a satisfactory degree of conversion. To facilitate oxidation of chlorotoluene, *p*-nitrotoluene, or toluic acid to the corresponding carboxylic acids, the following additional requirements must be met.

In the Amoco procedure, the addition of bromide to cobalt acetate and manganese acetate in acetic acid produces a highly reactive catalyst. *p*-Xylene is oxidized at 180 – 210 °C and 2 – 3 MPa (20 – 30 bar) using 0.1 wt % cobalt to a very pure terephthalic acid with a yield of over 95 % [12–14]. This catalyst is also suitable for the preparation of tricarboxylic and tetracarboxylic acids of benzene [15]. The reactors must be coated with a resistant material (enamel, titanium, nickel-chromium-molybdenum alloys such as Hastelloy-C4) because bromide ion is highly corrosive.

Carboxylic acids can be efficiently obtained by the *cooxidation* of alkyl-substituted aromatic compounds with reagents (acetaldehyde, butane, 2-butanone) which form peroxy radicals during the course of the reaction. Two procedures for the synthesis of terephthalic acid are based on this principle. The liquid-phase oxidation procedure operated by Eastman Kodak uses acetaldehyde [16], [17]. In the Toray process, a modification of the Kodak method, paraldehyde is employed instead of acetaldehyde. Butane and 2-butanone have been used as cooxidizing agents by Mobil Oil and Olin Mathieson [18]. These methods can also be efficiently applied to the oxidation of other alkyl-substituted aromatic compounds.

4. Polycarboxylic Acids and Anhydrides

4.1. Trimellitic Acid and Trimellitic Anhydride

Trimellitic acid crystallizes from water as needles (Table 1). It dissolves to the extent of 1.0 g in 100 g of acetic acid at 25 °C [19]. Trimellitic anhydride reacts with acetic acid and water and is hygroscopic (Table 2).

Trimellitic anhydride alone is of industrial importance. Its preparation is best achieved by the liquid-phase catalytic oxidation of 1,2,4-trimethylbenzene (pseudocumene) with air (Amoco method) [15], [20], [21]. An alternative process involves oxidation with 7 % nitric acid at 170 – 190 °C and 2 MPa, but it is inefficient compared with the air oxidation method [22].

The largest amount of trimellitic anhydride is used to make plasticizers for poly(vinyl chloride). These plasticizers have a lower volatility than phthalate plasticizers. Polyimides and polyesters of trimellitic anhydride have a high thermal resistance and are used in the production of wire enamels, coatings, and baking varnishes. The anhydride is an important curing agent in the production of epoxy resins. Polyester resins of trimellitic anhydride are widely used as paint resins for water-based and solvent-based coatings.

4.2. Pyromellitic Acid and Pyromellitic Dianhydride

Pyromellitic acid crystallizes from water as a dihydrate, triclinic plates, *mp* 242 °C (Table 1). Pyromellitic dianhydride is very hygroscopic (Table 2).

Pyromellitic acid was originally made by Du Pont by oxidizing 1,2,4,5-tetramethylbenzene (durene) with nitric acid. Today, the only method employed industrially is the vapor-phase oxidation of durene, trimethylisopropylbenzene, or dimethyldiisopropylbenzene to the dianhydride [23]. The oxidation conditions are similar to those used for *o*-xylene. The yield is approximately 60 %. Most of the applications require very pure pyromellitic dianhydride. Thus, the

Table 2. Anhydrides of aromatic carboxylic acids

Compound	Common name	Empirical formula	M_r	Chemical structure	*mp*, °C	*bp*, °C
1,3-Isobenzofurandione [*85-44-9*]	phthalic anhydride	$C_8H_4O_3$	148.12		131.2	215 (440 Pa) 284.5 (101.3 kPa)
1,3-Dihydro-1,3-dioxo-5-isobenzofuran-carboxylic acid [*552-30-7*]	trimellitic anhydride	$C_9H_4O_5$	192.13		168	390
1,3-Dihydro-1,3-dioxo-4-isobenzofuran-carboxylic acid [*3786-39-8*]	hemimellitic anhydride	$C_9H_4O_5$	192.13		196	
Benzo[1,2-*c*:3,4-*c'*]-difuran-1,3,4,6-tetrone [*4435-60-3*]	mellophanic dianhydride	$C_{10}H_2O_6$	218.12		198 sublimes	
Benzo[1,2-*c*:4,5-*c'*]difuran-1,3,5,7-tetrone [*89-32-7*]	pyromellitic dianhydride	$C_{10}H_2O_6$	218.12		285	390
Benzo[1,2-*c*:3,4-*c'*:5,6-*c''*]-trifuran-1,3,4,6,7,9-hexone [*4253-24-1*]	mellitic trianhydride	$C_{12}O_9$	288.13		310 (de-comp.)	sublimes at 200 °C (400–500 Pa)
Naphtho[1,8-*c,d*]pyran-1,3-dione [*81-84-5*]	naphthalic anhydride	$C_{12}H_6O_3$	198.18		276	422; sublimes at 215 °C (440 Pa)
[2]Benzopyrano[6,5,4-*def*][2]benzopyran-1,3,6,8-tetrone [*81-30-1*]	1,8:4,5-naphthalenetetra-carboxylic dianhydride	$C_{14}H_4O_6$	268.18		> 300	sublimes at 320 °C (400 Pa)
Perylo[3,4-*c,d*:9,10-*c',d'*]dipyran-1,3,8,10-tetrone [*128-69-8*]	perylene dianhydride	$C_{24}H_8O_6$	392.33		> 300	

raw substance must be freed from all impurities. Because of the high boiling point, purification by distillation is expensive and involves a large loss of material. Therefore, methods have been developed for the purification of pyromellitic dianhydride. Inert gases are passed through the raw product at a temperature above the dew point of the impurities (175 – 275 °C) [24], [25]. Complexes of dioxane or xylene are formed, isolated, and decomposed [26], and the impurities are dissolved and removed [27–29]. The only commercial producer is Chemische Werke Hüls AG with a capacity of 500 t/a.

The major part of the pyromellitic dianhydride produced is used in the production of polyimides that have excellent electrical and physical properties and a high heat resistance. Polyimide resins can be used for films, fibers, molding compounds, varnishes, and wire coatings. They are resistant to a constant temperature of 300 °C and a transient temperature of 500 – 600 °C. The trade names of these Du Pont products are Kapton (condensation product of pyromellitic dianhydride and 4,4′-diaminophenyl ether), Pyre-M 11, Pyralin, and Vespel.

4.3. Other Benzenepolycarboxylic Acids and Anhydrides

1,3,5-Benzenetricarboxylic acid, trimesic acid, is formed by the oxidation of 1,3,5-trimethylbenzene (mesitylene). This is carried out on an experimental scale (4.5 t/a) by the American Bio-Synthetic Corp. The applications are the same as those of trimellitic anhydride.

1,2,3-Benzenetricarboxylic acid (hemimellitic acid), hemimellitic anhydride, 1,2,3,4-benzenetetracarboxylic acid (mellophanic acid), mellophanic dianhydride, 1,2,3,5-benzenetetracarboxylic acid (prehnitic acid), benzenepentacarboxylic acid, benzenehexacarboxylic acid (mellitic acid) and mellitic trianhydride can all be obtained either by the air oxidation of the corresponding polymethylbenzenes using the Amoco process or by oxidation with nitric acid. The preparation of mellitic acid can also be achieved by the nitric acid oxidation of certain types of brown coal. None of these compounds is of commercial importance.

4.4. Naphthalic Acid and Naphthalic Anhydride

Naphthalic acid crystallizes as needles (Table 1). Naphthalic anhydride crystallizes from ethanol as needles (Table 2).

Naphthalic acid is prepared by the gas-phase oxidation of acenaphthene with air at 450 – 550 °C over a vanadium pentoxide catalyst. Yields of approximately 85 % are obtained. The mass-to-mass ratio of air to acenaphthene should be 80 – 100 to 1 [30]. The oxidation of acenaphthene can also be achieved in the liquid phase in acetic acid at 100 – 150 °C in the presence of cobalt, manganese, and bromide ion [31].

Naphthalic anhydride is primarily converted into imides or imide derivatives. Naphthalimide [*81-83-4*] (*mp* 300 °C) is formed by heating the anhydride in concentrated aqueous ammonia. Naphthalic anhydride is the starting material in the production of imidazole dyes. Imide derivatives are employed as optical brighteners for synthetic resins and fibers. Most naphthalimide is converted into derivatives of 3,4,9,10-perylenetetracarboxylic acid.

4.5. 3,4,9,10-Perylenetetracarboxylic Acid and Perylene Dianhydride

When heated, deep red 3,4,9,10-perylenetetracarboxylic acid (Table 1) yields red perylene dianhydride (Table 2).

When naphthalimide is heated to 220 °C with caustic potash [*1310-58-3*] and sodium acetate [*127-09-3*], the potassium salt of the leuco form of perylenetetracarboxylic diimide is formed. This product is subsequently oxidized in aqueous solution to form perylene diimide [*81-33-4*], $C_{24}H_{10}N_2O_4$, M_r 390.36, Perylene Bordeaux. The diimide in turn forms perylene dianhydride on hydrolysis with concentrated sulfuric acid at 215 °C [32], [33].

The diimide and the dianhydride are starting materials for the synthesis of aliphatic- and aromatic-substituted diimides. The latter constitute an important class of red dyes and pigments used in the production of color-fast plastics and coatings. Approximately 100 t/a of the dyes and 1000 t/a of the pigments are manufac-

tured worldwide (→ Naphthalimide Dyes and Pigments).

4.6. 2,6-Naphthalenedicarboxylic Acid

2,6-Naphthalenedicarboxylic acid, is prepared by using the Henkel procedure starting with the potassium salt of 1,8-naphthalenedicarboxylic acid or 2-naphthoic acid [34], [35].

The salt hydrolyzes readily to form the corresponding acid. Polycondensation of 2,6-naphthalenedicarboxylic acid with diols yields highly ductile and heat-resistant polyesters, which are used in the manufacture of films and fibers [36]. The product is suitable for magnetic tapes and electrical insulation materials.

4.7. 1,4,5,8-Naphthalenetetracarboxylic Acid and 1,8 : 4,5-Naphthalenetetracarboxylic Dianhydride

1,4,5,8-Naphthalenetetracarboxylic acid readily loses water when heated above 80 °C to form 1,8 : 4,5-naphthalenetetracarboxylic dianhydride.

The tetracarboxylic acid is obtained by the oxidative degradation of pyrene from coal tar. The oxidation proceeds in a series of steps [37], [38].

A new, technically feasible, procedure is based on the reaction of acenaphthene with diketene in liquid HF to yield 1,2-dihydro-7-methyl-cyclopenta [*cd*] phenalen-5-one [*42937-13-3*], $C_{16}H_{12}O$ [39].

This compound in turn can be converted to the dianhydride by air oxidation in acetic acid in the presence of ammonium vanadate and nitric acid as catalysts [40].

Most of the naphthalenetetracarboxylic dianhydride is condensed with two equivalents of *o*-phenylenediamine to give a mixture of *cis*- and *trans*-1,4,5,8-naphthoylene-bis(benzimidazole) (Indanthrene Scarlet GG), which when separated into the isomers yields Perinone Orange (trans), Indanthrene Brilliant Orange GR [*4424-06-0*], and Perinone Red (cis), Indanthrene Bordeaux RR [*4216-02-8*]. Both are used as pigments and vat dyes.

5. Economic Aspects

The benzene- and naphthalenepolycarboxylic acids are speciality items and are produced in comparatively small amounts. Amoco is the sole manufacturer of trimellitic anhydride in the United States; it has a production capacity of 25 kt/a. In 1983, the United States used 14 kt trimellitic acid ester as a special softener [41].

Chemische Werke Hüls is the sole supplier of pyromellitic anhydride. The production capacity is 500 t/a. The 1200 – 2000 t naphthalic anhydride produced in the EEC is all made by Chemische Fabrik Weyl (Germany). 1,4,5,8-Naphthalenetetracarboxylic acid is produced by Hoechst and by Toms River Chemical. The production capacity is less than 1 kt/a.

6. Toxicology

As a result of their acidity and their ability to dehydrate, the carboxylic acids and their anhydrides may cause severe irritation to the pulmonary tract, skin, eyes, and mucous membranes. Some compounds have additional toxic properties. Exposure to trimellitic acid may result in noncardiac pulmonary edema and immunological sensitization [42]. Pyromellitic

acid has an intraperitoneal LD_{50} in mice of 300 mg/kg. Pyromellitic acid inhibits the enzyme aconitase [43]. Handling precautions include effective ventilation, protective clothing, and goggles if exposure to dust is expected.

1. Introduction

Cancer incidences are increasing worldwide and in the industrialized countries malignant tumors are a leading cause of death, second only to cardiovascular diseases. Improvements in cancer treatment, surgery, pharmacological and radiation therapy, have not been able to reduce the threat that this illness is posing to the general public.

The term cancer covers a broad spectrum of malignant diseases that affect the blood-forming system in the bone marrow (leukemia, 4 % of human cancers), soft tissues and bones (sarcoma, 2 %), the lymphatic system (lymphoma, 5 – 9 %) and, most often, epithelial tissues including the skin, lung, gastrointestinal tract, and glands (carcinoma, 85 %).

Intensive investigations into the genesis of neoplasms have revealed a number of clues at the molecular level that may help in prevention and treatment of cancer.

[Top of Page]

2. Carcinogenesis

In most cases the induction of cancer is the consequence of low dose chronic exposure to carcinogenic agents and the process of carcinogenesis may take several years or even decades. A broad spectrum of mechanistic variations has been discovered. However, generally molecular biological investigations have confirmed the concept of carcinogenesis as being a multi-step process which is generally divided in the phases of initiation, promotion, and progression. On each of these phases carcinogenic agents may exert their specific activity and it has been possible in a few types of tumors to assign specific genetic changes in the process of transforming a normal, healthy cell into a malignant clone of tumorous cells (Fig. 1).

Figure 1. Carcinogenesis is a multi-step process. At any stage of this development carcinogenic agent may have an impact

Knowledge of the mechanisms of carcinogenesis may help to intervene in this process and reduce the incidence rates of cancer.

It is a biological fact that an increase in the number of tumors induced and/or a decrease of the latent period is observed with increasing dose of a carcinogen. For carcinogenic agents with a genotoxic mechanism, however, a no-effect dose cannot be defined. On the other hand, for carcinogens that act via nongenotoxic mechanisms thresholds are assumed. Thus, for the purpose of risk assessment it is pivotal to understand mechanisms of action in order to define possible threshold levels of exposure [1].

[Top of Page]

3. Genotoxic Mechanisms

The majority of carcinogenic agents acts as genotoxic agents, i.e., by damaging cellular DNA. These agents are termed mutagenic (see ⟶ Mutagenic Agents) or clastogenic.

3.1. Metabolic Activation

With few exceptions (see Section Alkylating Agents) carcinogenic organic chemicals (termed procarcinogens) are metabolically activated in the body to reactive metabolites (Fig. 2). These metabolic transformations are considered accidental in the general metabolism which improves hydrophilicity of foreign agents to facilitate their excretion from the body.

Figure 2. Metabolic activation of chemical carcinogens: Formation of electrophilic ultimate carcinogens. *N*-Nitrosodimethylamine (dimethylnitrosamine, DMNA) is activated via α-hydroxylation to a carbenium ion; polycyclic aromatic amines (2-aminonaphthalene, 2-AN) are oxidized and polycyclic aromatic nitro compounds (2-nitronaphthalene, 2-NN) are reduced to form a nitrenium ion; polycyclic aromatic hydrocarbons (dibenz[a,l]pyrene, DBP) are oxidized to form a dihydrodiol derivative and subsequently vicinal dihydrodiol epoxides in the fjord region of the molecule

Reactive metabolites formed may include radicals and most commonly electrophilic species (proximate or ultimate carcinogens). These may intermediately release positively charged ions that may react with nucleophilic components in the cell, such as H_2O or glutathione (a tripeptide containing cystein) resulting in a detoxification. These reactive species may also bind to cellular proteins leading to fatal cellular injury or the formation of immunogenic antigens. However, these electrophilic metabolic intermediates may also covalently modify the DNA in the cell nucleus.

3.2. DNA Binding

Several nucleophilic sites in the DNA have been identified as targets for covalent modification by electrophilic agents. DNA bases may be modified with preferential binding sites of alkylating agents (A), aromatic amines (AA) or polycyclic aromatic hydrocarbons (PAH).

The most prominent target of DNA binding is the base guanine where binding has been detected at positions N^7, O^6, N^2, and C^8, depending on the carcinogenic agent involved. These covalent modifications have been termed DNA adducts and may yield mutations in the genome upon DNA replication. The ability of an agent to form covalent DNA adducts is, thus, an indicator of its genotoxic activity and this damage may lead to the development of neoplasms. Although the formation of these DNA adducts is not sufficient for tumor development, all genotoxic agents identified as human carcinogens have been shown to bind covalently to DNA.

A form of indirect DNA damage is produced by reactive oxygen species (e.g., hydroxyl radicals) which may be formed by oxidants (Section Oxygen Damage) or by ionizing radiation (see Section Ionizing Radiation).

3.3. DNA Repair

The integrity of the genome is pivotal for the survival of a cell. Therefore, a highly sophisticated system of removal and repair of DNA lesions is at work in a cell to identify and remove modifications. Indeed, mechanisms have been identified (involving

the tumor suppressor gene *p53*) that arrest DNA replication and cell division in order to allow sufficient time for this repair to occur. Deficient DNA repair is often associated with an increased risk for developing cancer.

3.4. Molecular Targets in the Genome

Genetic targets for carcinogenic agents have been proposed that are termed proto-oncogenes or tumor suppressor genes. A number of these have been found to be frequently altered in tumor cells.

3.4.1. *Oncogenes*

Proto-oncogenes (⟶ Toxicology) are genes that encode for proteins implicated in vital functions of a cell. These gene products, e.g., growth factors, protein kinases, and receptors, are involved in signal transduction mechanisms. Certain mutations induced in these genes result in an activation of these proto-oncogenes: point mutations (change of one letter in the DNA code), amplifications (enhanced expression, i.e., production, of the gene product) or translocations (also resulting an increase in expression).

3.4.2. *Tumor-Suppressor Genes*

When mutations in a tumor-suppressor gene of a cell lead to a deletion of the encoded protein or the production of a nonfunctional protein this may result in the cell's expansion and unrestrained growth [2] (⟶ Toxicology).

[Top of Page]

4. Nongenotoxic Mechanisms

There are a number of carcinogenic compounds that induce cancer without possessing genotoxic activity. These agents act by various mechanisms and are summarized as *epigenetic carcinogens*. In contrast to the DNA damaging (genotoxic) agents, for epigenetic carcinogens doses can be established below which no adverse effects are expected to occur. These agents are often carcinogenic via mechanisms that involve acute toxic effects, thus, threshold levels of exposure can be defined.

4.1. Tumor Promoters

Tumor promoters are not carcinogenic on their own, but when applied subsequently to a (genotoxic) tumor initiator increase the number of tumors per animal or shorten the latency period of tumor development in an experimental setting. Thus, tumor promotion is an operational definition rather than a mechanistic concept. The biological phenomenon of tumor promotion is very specific for the animal species tested and the organ site of tumorigenesis, where mouse skin and rat liver are the most commonly tested organ sites. Mechanisms under consideration are mitogenesis (increased cell proliferation) and inflammatory processes.

Different from genotoxic mechanisms, promotion is considered to be reversible and threshold values for promoters are assumed to exist.

Prominent promoting agents are phorbol (4 β,9 α,12 β,1 α,20-pentahydroxy-1,6-tigliadien-3-one) esters [such as tetradecanoyl phorbol acetate (TPA) isolated from *Euphorbiaceae*], phenobarbital, saccharin, halogenated hydrocarbons (including DDT and other organochloro pesticides, polyhalogenated biphenyls (PCBs) and polyhalogenated dibenzodioxins/dibenzofurans (TCDD and congeners).

TCDD

DDT

Phenobarbital

BHT
2,6-di-*tert*-butyl-4-methylphenol
(butylared hydroxytoluene)

Saccharin

4.2. Hormones

Sexual hormones, mainly estrogens and progesterons, have been shown in animal experiments to increase the number of tumors at certain organ sites such as mammary gland, prostate, and endometrium. Tumor incidences in these organs are dependent on the sex; therefore, it is believed that a promoting effect of sex hormones is involved. The lifetime estrogen dose is considered a major factor for human breast cancer risk.

Steroid hormones are essential for the growth, differentiation, and function of many organs. Thus, the induction of cell proliferation is believed to be the mechanism by which steroid hormones act as carcinogenic agents.

In addition, genotoxic mechanism have been reported for estrogen, its metabolites, and related drugs (diethylstilbestrol, tamoxifen, cyproterone acetate).

A number of anthropogenic environmental contaminants have been discovered to have affinity to the estrogen or androgen receptor and to either mimic (agonists) or inhibit hormonal activity (antagonist). These xenoestrogens (hormonal disrupters) include polyhalogenated biphenyls, halogenated dibenzodioxins, and nonylphenol. Additionally, estrogen, its metabolites and anticontraceptive drugs (e.g., ethinyl estradiol) have been detected in sewage effluents.

Moreover, it has been shown that naturally occurring compounds may bind to the estrogen receptors. These compounds include flavonoids such as genistein and daidzein.

However, these exogenous hormones have generally a much lower affinity to the receptor than the endogenous hormones. Currently, it is unclear if these low levels of xenoestrogens and phytoestrogens have an impact on human endocrine homeostasis. A possible contribution to human cancer risk is a matter of speculation.

4.3. Peroxisome Proliferators

A considerable number of nongenotoxic agents that induce hepatic tumors in the rat have been shown to increase the number of peroxisomes in the rat liver. These cell organelles are responsible for the catabolism of long-chain fatty acids and cholesterols. During catabolism reactive oxygen species are produced in the hepatic cell and these may be the ultimate carcinogenic agents. Whether this mechanism may also play a role in human liver is a matter of dispute. Peroxisome proliferators include plasticizers (e.g., phthalates), halogenated organic solvents (1,1,2-trichloroethylene) and blood lipid lowering drugs (clofibrate, fenofibrate).

[Top of Page]

5. Identification of Carcinogenic Agents

In order to reduce cancer risk it is necessary (1) to identify the relevant agents and (2) to minimize exposure to these agents. The different approaches to identify the carcinogenic activity of an agent are outlined below. Ideally, both, experimental and human epidemiological data are available.

5.1. Animals Tests (in vivo)

In the National Toxicology Program in the United States and as a result of legislative requirements for new drugs and chemicals of a production volume of more than 1000 t/a in Europe, long term animal carcinogenicity studies are carried out. These two-year animal experiments are generally performed with rats, using several doses of the compound, including the maximum tolerated dose (MTD) which induces marginal toxic effects in the test animals. In the 1990s this concept has been challenged since this dosing regimen is generally several orders of magnitude higher than the anticipated human exposure and may produce many false positives because of toxic effects induced at the high doses [3].

Since this type of long term study is both labor- and cost-intensive, several approaches have been developed to introduce short-term in vitro or in vivo assays that may point towards a possible carcinogenic activity of a test substance.

5.2. In vitro Assays

Although the process of carcinogenesis may generally not be mimicked in a test tube or petri dish, several in vitro assays that are very sensitive in detecting genotoxic activity have been developed. These tests include microbial mutagenicity assays (e.g., the Ames test using various strains of *Salmonella typhimurium*, ⟶ Toxicology – The Ames Test for Bacterial Mutagenicity) and genotoxicity tests in mammalian cells. These in vitro assays are generally used as prescreening tests and may give hints on a possible carcinogenic activity of a test compound. They may also help in elucidating the mechanism of action of a rodent carcinogen.

More closely resembling the in vivo tumor induction are cell transformation tests. Here, the transformation of apparently normal cells into tumor cells is recorded as endpoint. These transformation tests are capable of detecting both, genotoxic and nongenotoxic carcinogens.

5.3. Modeling

Computer-assisted analysis of the results from several hundred rodent bioassays on the carcinogenic potency of organic chemicals has helped to identify certain structural elements as carcinogenic alerts [4]. These functional elements ("alerting structures") are listed in Table 1.

Table 1. Potential structural alerts for mutagenicity

Alkyl esters of phosphonic or sulfonic acids	Aromatic nitro groups	Aromatic amino groups	Aromatic hydroxylamines (+ esters)	Aromatic ring-N-oxides	Aromatic azo groups	Aromatic azides	Aromatic mono- or dialkyamino groups	
Alkyl hydrazines

Alkyl aldehydes

N-Hydroxymethyl groups

Monohaloalkenes

Halogenated methanes (X = H, F, Cl, Br, I)

CX_4

N- or *S*-mustard (β-haloethyl)

N-Chloramines

Propiolactone

Aromatic aziridinyl derivatives

Primary alkyl halides

CH_2Cl

Carbamates

N-Nitroso alkylamines

Michael reactive a, β-unsaturated aldehydes

Polycyclic aromatic hydrocarbons (bay regions)

Polycyclic aromatic hydrocarbons (fjord region)

Aliphatic and aromatic epoxides

However, even highly sophisticated calculation methods are presently not capable to replace biological testing.

5.4. Epidemiological Studies

Since experimental studies with possibly carcinogenic compound can, for obvious ethical reasons, not be performed with humans, data on human carcinogenicity have to be deduced by extrapolation from animal experiments, in vitro experiments (using human tissue or cells) and epidemiological studies.

Exposures may be occupational, environmental or accidental (see Chap. Forms of Exposure). Together with experimental studies such results may also provide insights into the mode of carcinogenic activity and biological plausibility. This combined approach is the most secure way of identifying a potential carcinogenic hazard [5].

5.5. Molecular Epidemiology

Conventional epidemiological investigations have been refined by mathematical improvements. However, as was pointed out by TAUBES [6] in a controversial paper these studies are only suitable to detect low risks for the general population and cannot be employed for individual risk assessment. A novel approach that takes into account the individual exposure levels and predisposing (e.g., genetic) factors has been termed molecular epidemiology [7]. By analyzing the internal dose (such as serum levels of a given compound) and/or metabolic capacities of individuals, this approach may help to identify both, subpopulations at risk and agents that pose a significant risk for human cancer.

[Top of Page]

6. Predisposing Factors

Several types of cancer are inheritable diseases. Since most cancer incidences occur at a late age past the reproductive age, the selective mechanisms of evolution do not help to eradicate these predispositions.

These inheritable forms of cancer account for less than 10 % of all cancer cases. More importantly, the predisposition to develop a malignant tumor may be inherited but is clinically manifest only when other factors such as exposure to specific carcinogenic agents occur. The mechanisms leading to an elevated individual risk include certain enzyme activities in the pathway of metabolic activation such as an enhanced enzyme activity with regard to toxification, a reduced activity in detoxification steps, or defects in DNA repair capacity. Individual risk is also a function of the levels of exposure to carcinogenic agents, the duration of this exposure, and the time in life when this exposure occurs (higher risk at young age) [7].

[Top of Page]

7. Classes of Carcinogenic Agents

7.1. *N*-Nitroso Compounds

Included in this group are the directly acting *N*-nitrosourea derivatives and the *N*-nitrosodialkylamines. The latter group requires metabolic activation (α-hydroxylation) to release an alkylating species that modifies the cellular DNA (see Fig. 2). *N*-Nitrosamines are among the most potent carcinogenic agents ever tested and *N*-nitrosodimethylamine has been detected in a variety of foods, industrial products, and the environment.

N-Nitrosamines may also be formed endogenously in the acidic environment of the stomach by nitrosation of alkylamines with nitrite. *N*-Nitroso derivatives of nicotine and related alkaloids contained in tobacco are formed upon combustion of tobacco (termed tobacco specific nitrosamines) and are considered major contributors to the carcinogenic potential of tobacco smoke.

7.2. Benzene

Benzene is a constituent of crude petroleum and motor gasoline and is produced in large quantities in the chemical industry as a synthetic intermediate. Both experimental and epidemiological studies have identified benzene as a human carcinogen inducing different forms of leukemia.

7.3. Polycyclic Aromatic Hydrocarbons

When organic matter such as fossil fuels, wood, tobacco, or waste is combusted, polycyclic aromatic hydrocarbons (PAH) are formed, especially under oxygen deficient conditions.

Members of this substance group were among the first individual compounds to be identified as carcinogenic agents. The carcinogenic potency varies among different PAHs depending on the number of aromatic rings and structural features. The most potent PAH are among the five- to six-ring compounds with benzo[*a*]pyrene being the prototype of a carcinogenic PAH. It was shown that PAHs require a multi-step metabolic activation process which results in the formation of dihydrodiol epoxide derivatives (Fig. 2). Genotoxic potency of these dihydrodiol epoxides is enhanced when activation occurs in a *bay region* or in a *fjord region* of a PAH molecule (Table 1) (see also ⟶ Tar and Pitch – Toxicology). Thus, PAHs with these structural features such as benzo[*a*]pyrene, dibenz[*a*,*h*]anthracene, or dibenz[*a*,*l*]pyrene have been shown to be most potent carcinogenic PAHs. Furthermore, biological activity of these diol epoxides varies with on the conformation of the different hydroxyl substituents.

7.4. Nitroaromatic Compounds

Associated with the occurrence of PAHs are their nitro derivatives. Relatively high levels of these compounds are observed in emissions of diesel-fueled motor vehicles. These compounds also require metabolic activation, the enzymatic process involves reduction of the nitro group to a hydroxyl function that results in a nitrenium ion as ultimate carcinogenic species (Fig. 2).

7.5. Aromatic Amines

Similar to aromatic nitro compounds aromatic amines are also transformed metabolically to hydroxyl derivatives, albeit via an oxidative pathway (Fig. 2). This class of carcinogenic compounds includes the monocyclic aromatic amines (aniline and its derivatives), polycyclic aromatic amines (e.g., 4-aminobiphenyl, ABP) and heterocyclic aromatic amines (e.g., aminoimidazo quinoxalines). A number of these aromatic amines are found in tobacco smoke and polycyclic amines such as 2-aminonaphthaline (β-naphthylamine), benzidine, and 4-aminobiphenyl have been associated with the increased risk of urinary bladder cancer observed among cigarette smokers. The high incidence of bladder cancer among workers in the dye industry has also been attributed to polycyclic impurities in aniline, namely 2-aminonaphthalene and 4-aminobiphenyl, but recently ortho-toluidine has also been considered as etiologic agent in these occupational cancers.

7.6. Halogenalkyls

Halogenated aliphatic hydrocarbons are widely used as solvents and industrial intermediates. These include halomethanes like CCl_4 and $CHCl_3$ that have been shown to induce liver tumors in rodents via nongenotoxic mechanisms. Dichloromethane induces tumors in lung and liver of mice; the significance of these findings for human cancer risk has been questioned.

Halogenated unsaturated hydrocarbons induce tumors in the kidneys of exposed rodents. A genotoxic mechanism involving a β-lyase mediated metabolic activation has been discovered.

Vinyl chloride (chloroethylene) the monomer of poly(vinyl chloride) (PVC) is an established liver carcinogen inducing hemangiosarcoma of the liver of exposed individuals.

Polyhalogenated cyclic hydrocarbons including pesticides (e.g., DDT and hexachlorocyclohexane), polyhalogenated biphenyls, polyhalogenated dibenzodioxins and dibenzofurans are exceptionally persistent in the environment. They are accumulated in the fatty tissues of animals and are enriched in the food chain. These compounds may act by various mechanisms as (nongenotoxic) tumor promoting agents.

Haloethers, such as bis(chloromethyl) ether or bis(chloropropyl) ethers, have been detected in substantial amounts in the environment as persistent contaminants. These ethers have a considerable carcinogenic potential.

7.7. Aldehydes

Formaldehyde is an ubiquitous chemical intermediate used in several fields of health sciences, in the production of synthetic resins, plastics and chip- and fiberboard. Formaldehyde is mutagenic and induces tumors in the rat (nasal cavity) following high level exposure. It has been suggested that the carcinogenic effect of formaldehyde in rodents is due to high-dose cytotoxic effects and there is inadequate epidemiological evidence of a carcinogenic potential in humans. Acetaldehyde and glutaraldehyde must be viewed similarly.

Unsaturated aldehydes such as crotonaldehyde may react with DNA bases to form cyclic DNA adducts and have been shown to be strongly carcinogenic in rodents.

7.8. Oxygen Damage

Reactive oxygen species are formed as a result of physiological cellular function. Glutathione and several enzymatic systems detoxify these reactive species (e.g., $OH^{\bullet}$) and guard the cellular function up to a certain level. Additional oxidative stress is imposed by chemicals that undergo one-electron oxidation or reduction in the cell forming radical species. This may lead to oxidative damage of DNA (e.g., 8-oxoguanine) that is usually effectively repaired but can also result in mutations. Indirectly, the oxidative damage of cellular lipids may lead to premutagenic lesions via modification of DNA by lipid peroxidation products. Oxidative damage of DNA has been proposed as a mechanism of heavy metal carcinogenesis. The carcinogenic effect of ionizing radiation is believed to be effected by the formation of reactive oxygen species.

Antioxidative compounds (such as α-tocopherol, vitamin E) may have an anticarcinogenic effect because they detoxify the reactive oxygen derivatives.

7.9. Alkylating Agents

Mustard gas (sulfur mustard) was used in large quantities in chemical warfare. Both experimental data and studies from occupational exposure indicate this DNA alkylating agent to be carcinogenic to humans. Similarly, there is sufficient evidence that alkylating antineoplastic drugs (cyclophosphamide ⟶ Cancer Chemotherapy – Cyclophosphamide, melphalan ⟶ Cancer Chemotherapy – Melphalan) increase human cancer risk (urinary bladder, leukemia) because the modification (alkylation) of cellular DNA is not restricted to the tumor but causes genotoxic damage in various organs of the patient.

7.10. Metals

There is indisputable evidence that beryllium, chromium, nickel, and arsenic represent a carcinogenic hazard to humans (pulmonary carcinoma and cancer of other organ sites), when present in certain well defined physicochemical forms. The evidence for the carcinogenicity of cadmium is less clear (probable targets are lung and prostate) although in the laboratory chronic inhalative exposure resulted in lung tumors in rats. Either way, cadmium compounds are very toxic in other respects (kidney and bones) so that they should be used with particular care.

The mechanism of metal carcinogenesis has tentatively been described as a genotoxic pathway since metal salts have been shown to be mutagenic in several in vitro short term tests.

Earlier misconceptions were based on a lack of mutagenic activity of these metals in the Ames test, the most widely used mutagenicity test. Other metals that are carcinogenic in laboratory animals include cobalt, iron, lead, titanium, and zinc.

With the exception of arsenic, metal carcinogenesis seems not to be a problem of environmental contamination at trace levels but is relevant to occupational exposure.

7.11. Natural Compounds

The pollution of the environment with synthetic chemicals has supported the notion that these anthropogenic substances are the major cause of human cancer. Natural compounds are generally considered as safe by the general public. However, as has been brought forward rather pointedly by AMES and coworkers there is a considerable number of substances of natural origin that have a strong carcinogenic potency. These authors hypothesize that natural agents are indeed far more relevant to human carcinogenesis than environmental contamination with synthetic substances.

Aflatoxins are produced by molds (*Aspergillus flavis*). Among these, aflatoxin B_1 is one of the most potent liver carcinogens in the rat and acts via a genotoxic pathway: after metabolic activation the epoxide reacts with guanine residues in the DNA. Molecular epidemiological studies have shown that in certain regions of east Africa (The Gambia and Senegal) and provinces of China the endemic high incidences of liver cancer are associated with aflatoxin-contaminated food in a synergistic combination with hepatitis B viral infection.

Carcinogens have also been detected in plants, e.g., phorbol esters [such as tetradecanoyl phorbol acetate (TPA) isolated from *Euphorbiaceae* or Aquilid A from bracken fern (*Pteridium aquilinum*)] and herbal drugs such aristolochic acid derived from birthwort (*Aristolochia* species), pyrrolizidine alkaloids (*Senecio ssp*), or anthraquinones (e.g., senna leaves). Nicotine in tobacco is a constituent of carcinogenic tobacco smoke (see Section Aromatic Amines).

Aristolochic acid I

Aflatoxin B_1

Pyrrolizidine

Emodin
(anthraquinone derivative)

Aquilid A

TPA

When proteinaceous food is grilled, fried, or broiled, heterocyclic aromatic amines are formed via the Maillard reaction. Among these, the aminoimidazo quinoxalines exhibit extremely strong mutagenic responses in the Ames test and have also been shown to induce tumors at several organ sites in rodents. Thus these heterocyclic amines are considered to be involved in human cancer at organ sites (colon, breast, prostate, pancreas) that are associated with a diet high in fried or grilled meat.

7.12. Hormones

See also Section Hormones.

Hormones include both endogenous sexual hormones, hormonal drugs, and environmental compounds with affinity to hormonal receptors. The latter can be of natural origin (phytohormones) or originate from anthropogenic environmental contaminants. The affinity to the hormonal receptors varies between different compounds by several orders of magnitude.

7.13. Mixtures

Humans are most often exposed to mixtures of carcinogenic agents, such as mixtures of polycyclic aromatic hydrocarbons in smoke or coal tar, mixtures of heterocyclic amines in fried meat or even complex mixtures of different types of chemical agents. These may act in an additive, synergistic (overadditive), or inhibitory manner. Since the composition of these complex mixtures is variable (for example, tobacco smoke or environmental pollution) it is difficult to predict quantitatively the biological potency of such complex mixtures. One of the most complex and most important chemical mixtures is the human diet.

7.14. Mineral Fibers (⟶)

Dust of the naturally occurring rock asbestos, particularly blue asbestos (crocidolite) can induce mesothelioma (malignant tumors of the pleura) following inhalative exposure. The physical properties of the needle-like fibers (length > 5 µm, diameter < 3 µm) and the very long biological half-life are crucial for the activity. Thus, other fibers (erionite, a zeolite mineral) with similar properties have also carcinogenic potential.

Other synthetic inorganic fibers (rock wool, glass fibers, ceramic fibers) are less persistent in the body; probably for this reason the carcinogenic potential of these is less certain.

7.15. Viruses and Other Biological Agents

Viral infection is a major risk factor for human cancers, chronic infection with specific viruses being implicated in the genesis of up to 20 % of tumors.

Retroviruses.
HTLV-I. has been implicated as a cause of adult T-cell leukemia/lymphoma; less than 4 % of individuals infected with this virus develop the tumor, and then only several decades after the initial infection.

HIV-1, HIV-2. The increased incidence of lymphoma and Karposi's sarcoma in patients infected with human acquired immune deficiency syndrome (AIDS) viruses is almost certainly the result of the chronic immunosuppression that occurs in the disease, rather than a direct oncogenic effect.

DNA and RNA Viruses. Chronic infection with human papilloma virus (HPV), acquired as a result of sexual transmission , has been implicated as a cause of cervical, anal, and vulval cancer. HPV is present in more than 60 % of cervical carcinomas, and additional risk factors such as herpes simplex virus and smoking, seem to be necessary.

Hepatitis B Virus (HBV) and Hepatitis C Virus (HCV). Epidemiological evidence links chronic infection with HBV or HCV to the development of hepatocellular carcinoma. It has been suggested that these viruses may induce liver cancer indirectly, acting as a promoter by causing chronic inflammatory liver disease.

Herpes Viruses. Epstein Barr virus (EBV) may be involved in the pathogenesis of a number of human tumors, including Burkitt's lymphoma, Hodgkin's disease and salivary gland, urogenital or nasopharyngeal carcinoma. In AIDS patients, lymphomas (immunoblastic and nervous system) are also associated with this virus.

Parasites. Schistosomiasis, a parasitic infection with different types of the flatworm *Schistosoma* is endemic in different tropical regions of the world and is associated with an increased risk of cancer of the urinary bladder. Chronic inflammation of the bladder and metabolic changes leading to increased endogenous formation of *N*-nitrosamines is being considered as mechanism of action.

Bacterial Infection. Infection with *Heliobacter pylori* is believed as causally involved in human stomach cancer.

7.16. Nonionizing Radiation

Skin cancer is the most common neoplasm in Caucasians in the United States with a lifetime risk nearly equal to that of all other cancers combined. Sun exposure is the major environmental agent implicated in induction of nonmelanoma skin cancer (basal cell carcinoma or squamous cell carcinoma).

The initiating event is the DNA damage induced by UV radiation: cross-linking of two thymidine bases to form a cyclobutane ring (2 + 2-cycloaddition). This hypothesis is corroborated by the observation that patients with the rare inherited disorder *Xeroderma pigmentosum* have a skin cancer risk 1000 times higher than that of the general population, probably due to a defect in DNA nucleotide excision repair.

With the reduction of the stratospheric ozone layer, UV exposure is increasing and skin cancer rates are rising. Preventing severe sunburn especially at young age and regular medical checkups are important to minimize the risk.

7.17. Ionizing Radiation

Long term follow-up of survivors of the atomic bomb releases in Hiroshima and Nagasaki, as well as of patients that received extensive radiation therapy provided epidemiological evidence that ionizing radiation can induce cancer in any organ in which cancer occurs naturally. In particular the rate of leukemia, cancer of the breast, lung, and thyroid are increased with latency periods up to 20 years. Most pronounced effects were observed when the exposure to a single high dose of radiation occurred at a young age.

Radiation may cause DNA damage indirectly: formation of reactive radicals by radiochemical homolysis of water molecules and induction of DNA strand breaks by these reactive intermediates.

The relationship between cancer and low-level radiation is a subject of much controversy. The considerable level of natural background radiation has been said to exceed the low levels of exposures such as in the vicinity of nuclear power or reprocessing plants. Recently, the observation of inheritable genomic instability induced by low amounts of radiation has been discussed.

7.18. Electromagnetic Fields

The increase of electrical appliances in the home, the widespread use of mobile phones, high tension lines and the constant exposure to computer monitors and television sets results in an exposure of the human body to electromagnetic fields. These fields are not without biological effects; however, the proposed carcinogenic (promoting) effects of extremely low frequency (0 – 300 Hz) electromagnetic fields have not been definitely confirmed experimentally.

[Top of Page]

8. Human Carcinogens

The evidence provided by epidemiological data is currently taken as the only acceptable proof for a given compound to be a human carcinogen. It is a matter of controversy whether or to what extent experimental data, e.g., from rodent assays may be regarded as adequate data to classify a compound a human carcinogen.

It has been pointed out that standard testing at the MTD results in a number of false positives, e.g., many agents are labeled carcinogenic only because of the cytotoxic action at unrealistic high doses [1], [3]. The International Agency for Research on Cancer (IARC) has evaluated a number of agents [5]. These are listed below and are classified according to the IARC categorization scheme:

Carcinogenic to humans (Group 1): a causal relationship has been established between the exposure and human cancer

Chemicals and groups of chemicals
Aflatoxins
4-Aminobiphenyl
Arsenic and Arsenic compounds
Asbestos

Benzene
Benzidine
Bis(chlormethyl)ether
Chromium compounds (hexavalent)
Erionite
Mustard gas (sulfur mustard)
2-Naphthylamine
Nickel compounds
Radon and its decay products
Talc containing asbestiform fibers
Vinyl chloride

Mixtures

Alcoholic beverages
Betel quid with tobacco
Coal-tar pitches
Coal tar
Mineral oils
Shale oils
Soots
Tobacco products, smokeless
Tobacco smoke

Drugs

Analgesic mixtures containing phenacetin
Azathioprine
N,*N*-Bis(2-chloroethyl)-2-naphthylamine (Chlornaphazine)
1,4-Butanediol dimethanesulfonate (myleran)
Chloroambucil
1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrososurea (Methyl-CCNU)
Cyclophosphamide
Cyclosporin
Diethylstilbestrol
Melphalan
8-Methoxypsoralen plus UV radiation
Estrogen replacement therapy
Estrogens, nonsteroidal
Estrogens, steroidal
Thiotepa
Treosulfan

Biological and physical factors

Hepatitis B virus
HTLV 1
Ionizing radiation
Ultra-violet radiation

Probably carcinogenic to humans (Group 2A): a positive association has been observed, a causal interpretations credible, but chance bias or confounding factors cannot be ruled out with confidence; sufficient evidence of carcinogenicity in animals);

Chemicals and groups of chemicals

Acrylonitrile
Benzo[*a*]anthracene
Benzidine-based dyes
Benzo[*a*]pyrene
Beryllium and beryllium compounds
Cadmium and cadmium compounds
p-Chlorotoluidine
Dibenz[*a*,*h*]anthracene
Diethyl sulfate
Dimethylcarbamoyl chloride
Dimethyl sulfate
Epichlorohydrin
Ethylenedibromide
Ethylene oxide
N-Ethyl-*N*-nitrosourea
Formaldehyde
4,4'-Methylene-bis(2-chloroaniline) (MOCA)
N-Methyl-*N*'-nitro-*N*-nitrosoguanidine (MNNG)
N-Methyl-*N*'-nitrosourea
N-Nitrosodiethylamine
N-Nitrosodimethylamine
Propylene oxide
Silica, crystalline
Styrene oxide
Tris(2,3-dibromopropyl)phosphate
Vinyl bromide

Mixtures

Creosotes

Diesel engine exhausts
Polychlorinated biphenyls
Drugs
Adriamycin
Anabolic steroids
Azacytidine
N,N'-bis(2-chloroethyl)-*N*-nitrosourea (BCNU)
Chloramphenicol
N-(2-chloroethyl)-*N'*-cyclohexyl-*N*-nitrosourea (CCNU)
Chlorototocin
Cisplatin 5-Methoxypsoralen
Nitrogen mustard
Phenacetin
Procarbazine hydrochloride
Tris(1-aziridinyl)phosphine sulfide (Thiotepa)
Biological factors
Clonorchis sinensis
Epstein Barr virus
Herpex simplex virus 2
Human immunodeficieny viruses
Human papilloma virus
Opisthorchis viverini
Schistosoma haematobium

Possibly carcinogenic to humans (Group 2B): sufficient evidence of carcinogenicity in animals, but no adequate data on cancer in exposed humans)
Not classifiable as to its carcinogenicity to humans (Group 3)
Probably not carcinogenic to humans (Group 4)

Other classification schemes by other organizations exist including those of the EPA, the EC, or the Chemical Manufacturers Association. These evaluations agree with respect to the classification of compounds that are known human carcinogens but place different emphasis on the results of animal or in vitro studies. These lists of agents with an established carcinogenic effect may help to avoid or at least reduce exposure to these substances. However, it cannot be assumed that substances not included in these lists are nonhazardous; it may simply be a lack of data on humans.

[Top of Page]

9. Forms of Exposure

9.1. Occupational Exposure

Historically, human occupational exposure to relatively high doses of chemical carcinogens has provided insight into the etiology of human cancer. The earliest observations were reported by POTT (1775) on an increased risk of scrotal cancer in chimney sweeps or by REHN (1897) who observed an elevated incidence of tumors in the urinary bladder among workers of the dye industry [8].

Whereas for high exposure levels at the workplace (asbestos, metals) often a clear epidemiological evidence exists for the carcinogenicity of certain substances, such causal relationships are difficult to verify for environmental (low level) exposures. In the developed countries, but less so in the developing or newly industrialized countries [9], safety precautions in the industry have been implemented by law and have resulted in a reduced levels of exposure and subsequently in lower incidences of occupational cancer.

9.2. Environmental Exposure

Many carcinogenic agents identified in an occupational setting can also be found in the general environment at lower levels. One example of these is asbestos. Whether the low levels of carcinogenic compounds in the general environment pose a significant cancer risk is a matter of intensive debate. It has been brought forward that the risk calculated from animal carcinogenicity data and environmental exposure levels is very low and may statistically effect only few people. On the other hand, individual differences in susceptibility and combination effects resulting from exposure to complex mixtures must be considered.

For genotoxic compounds the general assumption is that there is no threshold. For nongenotoxic carcinogenic agents biological considerations, that take into account the mechanisms of action, point towards the existence of a threshold dose. However, determination of threshold levels for chronic biological effects is a formidable task [1], [5].

9.3. Lifestyle

Perhaps the most common cause of human cancer is tobacco smoking and other forms of tobacco abuse (chewing, sniff). It has been estimated that over 90 % of lung cancer and significant proportions of cancers at other organ sites (urinary bladder, pancreas, gastrointestinal tract, upper respiratory passages) are attributable to excessive tobacco smoking. Overall, about one-third of all cancer deaths are believed to result from this habit [1], [5], [10]. Accordingly, it has been convincingly demonstrated that smoking cessation reduces the cancer risk significantly.

The carcinogenic effect of excessive intake of alcoholic beverages is not as readily apparent. However, the risk for cancer of the oral cavity or the larynx increases markedly when an individual smokes tobacco and abuses alcoholic beverages. Similarly, a synergistic effect has been observed for liver cancer when individuals infected with hepatitis B virus consume alcoholic beverages excessively [5].

Viral infections (e.g., HIV, HPV) are associated with promiscuity. Here, the use of protective measures upon sexual intercourse has been shown to reduce the risk of an infection (see Section Viruses and Other Biological Agents)

9.4. Diet

Dietary factors have been considered to be most important among the different contributors to human cancer [10], [11]. In the diet, carcinogenic agents can be found such as PAH and heterocyclic amines in grilled meat, carcinogenic plant products (safrol) or mycotoxins (see Section Natural Compounds). A high calorie diet and/or a diet high in fat (especially saturated animal fat) has been shown to increase tumor formation in experimental animals but epidemiological evidence is insufficient. There are also speculations on factors with anticarcinogenic activity such as antioxidants, vitamins, and fibers.

9.5. Drugs

Among the cytostatic drugs used in the chemotherapy of neoplasms several classes of compounds exist that have been shown to induce tumors in rodents or even lead to the induction of secondary tumors in treated patients. These include alkylating agents [mitomycin C, cyclophosphamide and nitrosourea derivatives (BCNU)], and anthracyclines (doxorubicin).

Genotoxic activity has been reported for hormone drugs (cyproterone acetate, tamoxifen) while a postulated increase in tumor incidences as a result of continued use of contraceptive drugs was not confirmed by epidemiological studies. Diethylstilbestrol, a synthetic estrogen used in the 1960s to prevent spontaneous abort, induced carcinoma in the children of treated patients.

Various drugs such as phenacetin that have been identified as carcinogenic agents have been withdrawn from the market. A number of herbal drugs contain carcinogenic components including aristolochic acid, anthraquinones, and pyrrolizidine alkaloids (see Section Natural Compounds).

9.6. Exposure Levels in Developing Countries

To some extent, industry is being forced to develop cleaner and safer processes and products in North America and Europe. However, in the rapidly industrializing countries of the Third World, corporate responsibility is not compelled by public awareness, regulation, and compensation laws. It has been pointed out not only by industry critics but also the International Labor Office and the United Nations Center on Transnational Corporations that global corporations are operating more polluting and dangerous plants in Third World countries [12]. Carcinogenic or otherwise toxic chemicals, e.g., pesticides such as DDT, banned for certain uses or voluntarily withdrawn from markets in the United States or Europe, are being produced and marketed in Africa, Asia, and Latin America. In small-scale industries that account for the bulk of industrial enterprises in developing and newly industrialized countries the standards of industrial hygiene, safety and, waste management are low [9].

With the industrialization the western lifestyle is adopted in these countries; thus, developing and newly industrialized countries are the fastest growing markets for the tobacco industry. It has been predicted that here the rates of lung cancer are going to increase in an exponential way in the years to come [13].

9.7. Safe Handling of Carcinogenic Agents

For laboratory handling of chemical carcinogens, the U.S. National Research Council has provided useful guidelines [14]. Because the toxicological properties of most laboratory chemicals are undetermined, virtually all operations should be performed in well-ventilated fume-cupboards. Care should be taken to avoid contact with the skin and to avoid ingestion even of traces. Additional precautions are to be taken for the handling of chemicals with high carcinogenic potency. National or federal legislation regulates the appropriate labeling of carcinogens, suspected carcinogens (see Table 1) and other hazardous chemicals; these should be handled only by trained persons.

1. Introduction [1–5]

Blood circulation is effected by the rhythmic sequence of atrial and ventricular contraction (systole) and relaxation (diastole) of the heart. *Heart failure* is an abnormality in cardiac performance that prevents the heart from pumping blood at a rate commensurate with the metabolic and circulatory demands of the body.

Various compensatory mechanisms maintain a relatively normal cardiac output in the early stages of insufficiency; they are responsible for the symptoms of chronic congestive heart failure described in the following.

Sodium and water retention increase the blood volume and lead to elevated venous pressure, pulmonary vascular congestion, and peripheral edema. Increased adrenergic stimulation produces an increase in heart rate (tachycardia) and a constriction of blood vessels (vasoconstriction). In left-side heart failure, pulmonary capillary pressure increases. Edema and venous congestion increase the work of breathing, resulting in shortness of breath (dyspnea), fatigue, and weakness. If the capillary pressure exceeds a critical value, life-threatening acute pulmonary edema develops. Elevated systemic venous pressure in right-side heart failure is accompanied by peripheral congestion, resulting in ankle edema and enlargement of the liver.

Congestive heart failure develops secondary to an increase (1) in cardiac ventricular pressure and (2) in the size of cardiac ventricles. This occurs if the heart must cope for an extended period of time with an abnormally high demand upon cardiac contractility. This demand may be caused by cardiovascular disease (hypertension, myocardial ischemia), cardiomyopathy, or congenital heart disease. Knowledge of the cause of heart failure at the cellular and molecular level is based on growing information on the contractile proteins of the heart muscle. Hypotheses focus on disturbances in mitochondrial energy production and conversion of chemical energy into mechanical work in the contraction process.

Congestive heart failure affects about five million people in the United States. The New York Heart Association has developed a classifi-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a05_271

cation of patients on the basis of the relationship between symptoms and the amount of physical effort required to provoke them:

Class I. No limitations: ordinary physical activity does not cause undue fatigue, dyspnea, or palpitation.
Class II. Slight limitation of physical activity: patients are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or angina.
Class III. Marked limitation of physical activity: although patients are comfortable at rest, less than ordinary activity will lead to symptoms.
Class IV. Inability to carry on any physical activity without discomfort: symptoms of congestive heart failure are present even at rest. With any physical activity increased discomfort is experienced.

Therapy [6] should be aimed primarily at the determination and possibly the elimination of the underlying cause, e.g., by surgical correction of valvular lesions, alleviation of infection or arrhythmia, or chemotherapeutic treatment of hypertension. Treatment of heart failure usually starts with simple measures; these include decreasing the demands on the heart by reducing physical activities and restricting the intake of sodium. Drug treatment of congestive heart failure must increase cardiac output and relieve pulmonary congestion and peripheral edema. This may be achieved by the following:

1) treatment with diuretics to reduce volume overload (→ Antihypertensives)
2) stimulation of myocardial contractility with cardiotonic agents, particularly with cardiac glycosides
3) adjustment of peripheral circulation with peripheral vasodilators (→ Antihypertensives)

Drugs that inhibit the angiotensin converting enzyme (ACE inhibitors) are the vasodilators of choice for the treatment of congestive heart failure.

Positive Inotropic Agents. Drugs that stimulate myocardial contractility are called positive inotropic agents, or cardiotonic agents. The oldest and still most important drugs for the therapy of congestive heart failure are the cardiac glycosides.

Such classical sympathomimetics as epinephrine are not used for the treatment of chronic heart failure; their inotropic activity is high but only transient, and it is combined with an increase in heart frequency, vasoconstriction, and an excessive myocardial oxygen demand.

Since the 1970s new positive inotropic agents including orally active sympathomimetic agents and a group of drugs that act predominantly by increasing cyclic adenosine monophosphate (cAMP) – either as inhibitors of phosphodiesterase type III (amrinone, milrinone) or by stimulating cAMP formation (forskolin) – have been investigated thoroughly. Although some of these compounds are used for the treatment of acute heart failure, their utility in the long-term treatment of congestive heart failure could not be established.

Mode of Action. All hypotheses concerning the mode of action of positive inotropic agents are based on the assumption that these drugs affect contractility by raising the intracellular Ca^{2+} concentration. This effect is best understood by considering the structural elements of the heart that are responsible for contractility [7–9]. The fundamental contractile units of heart muscle cells – the longitudinally arranged myofibrils – are made up of the contractile proteins *actin* and *myosin* and the regulatory proteins *tropomyosin* and *troponin*. Contraction and relaxation are effected by sliding the thin filaments, which contain actin aggregates, with respect to the thick filaments of myosin chains (sliding filaments theory). In the relaxed state troponin and tropomyosin inhibit the interaction of actin and myosin. Initiation of the contracting process occurs after binding of Ca^{2+} to troponin and subsequent change of the position (conformation) of the troponin–tropomyosin complex to allow for the interaction of actin and myosin.

This hypothesis accounts for the well-known importance of Ca^{2+} in the contraction process in heart muscle cells. Rapid increase in intracellular Ca^{2+} concentration from 10^{-7} mol/L during relaxation to 10^{-5} mol/L during contraction is regulated by the action potential of cardiac cells. Increase in available intracellular Ca^{2+} is triggered by a slow influx of Ca^{2+} during the plateau phase of the myocardial action potential. Together with an increase in intracellular Na^{+}, this causes the release of additional Ca^{2+} from

internal stores. Because of the importance of free Ca^{2+} for excitation–contraction coupling, the regulation of the intracellular concentration of Ca^{2+} explains all phases of the mechanism of action of cardiac glycosides and other inotropic agents.

Despite their different modes of action, all inotropic agents act by increasing the force of contraction of the heart to produce a higher cardiac output. Figure 1 shows ventricular function curves in healthy humans and in those with congestive heart failure. In the second group a normal cardiac output *N* can only be achieved at the expense of an elevated end diastolic pressure (Frank–Starling mechanism). Treatment with cardiac glycosides or other inotropic agents shifts the curve of the failing heart upward toward normal so that the required output *N* can be delivered at a lower end diastolic pressure and without the symptoms of congestive heart failure.

Figure 1. Ventricular function curves of the normal heart and the failing heart before and after treatment with cardiac glycosides according to ref. [10]

2. Cardiac Glycosides

Cardiac glycosides (synonyms: digitalis, cardiac steroids, cardiac poisons) are closely related natural products, found in a variety of plants [11], [12]. Some of them have been used as poisons and drugs since ancient times. The systematic use of cardiac glycoside preparations for the therapy of cardiac insufficiency and associated edema dates back to 1785, when W. WITHERING published his paper "*An Account of the Foxglove and Its Medical Uses.*" Of the more than 400 different cardiac glycosides that have been isolated from natural sources, only about 10 are used in therapy.

The pharmacology of cardiac glycosides involves a complex set of direct and indirect effects [13–16]. Their most important effect is to enhance the force and velocity of myocardial contraction (*positive inotropic effect*). In addition, cardiac glycosides decrease the rate of the failing heart (*negative chronotropic effect*); since ventricular tachycardia is common during heart failure, this effect is of great value in practical therapy. Digitalis depresses atrioventricular nodal conductivity (*negative dromotropic effect*), but it may also increase myocardial excitability and automaticity (*positive bathmotropic effect*), leading to the development of arrhythmias.

Because of their very narrow therapeutic range, therapy with cardiac glycosides is difficult. In some patients toxic symptoms are observed at doses that are required to compensate the failing heart at least partially. The toxicity of cardiac glycosides comprises both cardial and extracardial effects. Cardiac toxicity produces arrhythmias, leading in severe cases to ventricular fibrillations with subsequent systolic arrest and death. Extracardial symptoms include gastrointestinal disorders, mental changes, and visual disturbances.

Despite the introduction of new therapeutic strategies in the treatment of congestive heart failure and some uncertainty concerning their risk – benefit ratio and their long-term effects on survival [17], cardiac glycosides are still widely used, particularly in the elderly. In the United States digoxin (Lanoxin) belongs to the ten most frequently prescribed drugs [18].

2.1. Chemical Structure [11], [19–24]

The structures of cardiac glycosides are represented by one of the general formulas (**1**) to (**3**), in which a steroid (aglycone) is linked through an alcoholic hydroxyl group with the hemiacetal form of a mono-, di-, tri-, or tetrasaccharide:

Aglycones. Cardioactivity resides in the steroidal aglycone, also called the genin. The saccharide moiety modifies potency and contributes mainly to the pharmacokinetic properties. Characteristic structural features of cardioactive steroids are the cis fusion of the rings A/B and C/D, a tertiary hydroxyl group at C-14, and an axially oriented hydroxyl group at C-3 which mediates the attachment of the sugar residue. An unsaturated lactone ring is joined to the steroid nucleus at C-17 (see structure of digitoxigenin).

Steroids carrying an α,β-unsaturated five-membered lactone ring (butenolide ring) and their corresponding glycosides are called *cardenolides.* The best known representative of this type is *digitoxigenin*:

A six-membered, doubly unsaturated α-pyrone ring is characteristic of the *bufadienolides,* e.g., bufalin (3,14-dihydroxybufa-20,22-dienolide):

All naturally occurring cardioactive steroids are derived from these two basic structures. Additional hydroxyl groups may be at C-1, C-5, C-11, C-12, and C-16. Replacement of the C-10 methyl group by hydroxymethyl or an aldehyde function is found in certain glycosides of the strophanthus series. Another variation is the introduction of a double bond between C-4 and C-5. A survey of the most important aglycones from which essentially all naturally occurring glycosides are derived is given in Table 1.

Sugars of Cardiac Glycosides. [25]. Sugars include D-glucose, L-rhamnose, and a number of rare 6-deoxy- and 2,6-dideoxy sugars and their 3-*O*-methyl derivatives. The sugars of the D series are linked to the genin by a β-glycosidic bond and adopt the C 1 conformation; the L sugars occur as α-glycosides in the 1 C conformation (Table 2) [26], [27].

Table 2. Sugars of cardiac glycosides. d-Sugars are represented in the C 1 conformation of their β-d-hexopyranose form, l-sugars in the 1 C conformation of their α-l-hexopyranose form

β-D-Glucose

β-D-Thevetose (6-deoxy-3-*O*-methyl-β-D-glucose)

β-D-Digitoxose (2,6-dideoxy-β-D-ribo-hexose)

β-D-Cymarose (2,6-dideoxy-3-*O*-methyl-β-D-ribo-hexose)

α-D-Rhamnose

α-L-Oleandrose 2,6-dideoxy-3-*O*-methyl-α-L-arabino-hexose)

In cardiac glycosides derived from oligosaccharides, the sugars are joined either through a $1 \rightarrow 4$ or a $1 \rightarrow 6$ glycosidic linkage. Representative examples of the different structures of naturally occurring cardiac glycosides are digitoxin, *k*-strophanthoside, and scillaren (see Table 3).

The natural glycosides have one or two molecules of glucose attached to the end of the saccharide chain. They are called *genuine* or *primary glycosides.* These glucose residues are easily split off by specific glucosidases, which occur in plant sources of cardiac glycosides, to give the *secondary glycosides.* This enzymatic conversion may take place during prolonged storage

Table 1. Aglycones of cardiac glycosides

Cardenolides: R =

Bufadienolides: R = 
Aglycone	CAS reg. No.	Substituents

or in the course of the extraction procedures unless care is taken to inactivate these enzymes.

2.1.1. Cardenolides

Digitalis Glycosides. The leaves and seeds of the purple foxglove (*Digitalis purpurea*) and the woolly foxglove (*Digitalis lanata*) from the Scrophulariaceae family are the most important sources of cardiac steroids. The dried leaves contain up to 0.3 % (*D. purpurea*) or 1 % (*D. lanata*) of a complex mixture of cardioactive glycosides.

The main genuine glycosides of *D. lanata* are lanatosides A, B, and C, which are derived from the aglycones digitoxigenin, gitoxigenin, and digoxigenin, respectively. Their oligosaccharide part is made up of three molecules of digitoxose and one glucose at the end of the chain. The 3-hydroxyl group of the third digitoxose (3‴-position) is acetylated.

The main glycosides of *D. purpurea* are purpurea glycosides A and B, together with the 16-formyl derivative of purpurea glycoside B. Their structures differ from those of the lanatosides only by the absence of the acetyl group. Remarkably, a glycoside derived from digoxigenin, corresponding to deacetyl-lanatoside C, is not present in the purple foxglove. Some reactions and interconversions of digitalis glycosides are shown in Figure 2.

Table 3. Representative examples of naturally occurring glycosides

Digitoxin

k-Strophanthoside

Scillaren

Structurally related to the digitalis glycosides is oleandrin [*465-16-7*], a gitoxigenin derivative from the white oleander (*Nerium oleander*):

Oleandrin

The seeds of the South American tree *Thevetia neriifolia* (yellow oleander) are an especially rich source of glycosides.

Thevetin A: R = CHO
Thevetin B: R = CH_3

In addition to the main glycoside thevetin B [*27127-79-3*], the seeds contain thevetin A [*37933-66-7*] which gives peruvoside upon enzymatic removal of glucose.

Strophanthus Glycosides. Extracts from the seeds and wood of trees of the genus *Strophanthus,* growing in tropical regions of Africa and Asia, contain powerful cardiac glycosides and have long been used as arrow poisons. Ouabain (*g*-strophanthin) [*11018-89-6*] is readily isolated from the seeds of *S. gratus* in 3 – 4 % yield.

Ouabain

The genuine glycoside from *Strophanthus kombé* is *k*-strophanthoside [*33279-57-1*]. Stepwise enzymatic degradation with glucosidase and strophanthobiase leads to *k*-strophanthin-β [*560-53-2*] and then to cymarin [*508-77-0*]:

k-Strophantoside: R = β-D-cymarose-(β-D-glucose)$_2$
k-Strophantoside-β: R = β-D-cymarose-β-D-glucose
Cymarine: R = β-D-cymarose

Also derived from the same aglycone and structurally related to the strophanthus glycosides is convallatoxin [*508-75-8*], a glycoside found in the leaves and blossoms of lily of the valley (*Convallaria majalis*):

Convallatoxin

Figure 2. Main glycosides from *Digitalis lanata* and *Digitalis purpurea*
[a]R^1, R^2 = H; [b]R^1 = H, R^2 = OH; [c]R^1 = OH, R^2 = H

2.1.2. Bufadienolides

Bufadienolides are found as glycosides in some plants of the Liliaceae and Ranunculaceae families. Related to these glycosides are the toad poisons, which occur as the free genins or are combined with suberylarginine. The most important source of bufadienolide glycosides is the white squill (*Scilla maritima, Urginea maritima*) from the Mediterranean region and India. The bulb of the white squill contains up to 0.3 % of a mixture of cardioactive components, principally scillaren [*124-99-2*]. Proscillaridin [*466-06-8*] is obtained upon enzymatic hydrolysis of this mixture with scillarenase:

Proscillaridin

Scilliroside, the main component of the red squill, is not used therapeutically, but is worth mentioning because of its high toxicity to rats.

The roots of the Christmas rose (*Helleborus niger*) yield glycosides derived from the aglycone hellebrigenin [*465-90-7*].

2.2. Isolation, Chemical Synthesis

Efficient isolation procedures, structural elucidations, and total syntheses are due to pioneering work on the chemistry of cardioactive steroids in the groups of A. Windaus, W. A. Jacobs, R. C. Elderfield, H. Wieland, T. Reichstein, A. Stoll, R. Tschesche, K. Meyer, F. Sondheimer, H. Ruschig, D. Satoh, G. R. Pettit, K. Wiesner, and G. Stork.

Isolation is tedious because cardiac glycosides occur in plants only in small amounts and as complex mixtures. In addition, the crude plant material usually contains enzymes that split off glucose from the native glycosides, leading to partial degradation. Inhibition of these enzymes with ammonium salts is essential to isolate the genuine glycosides.

For the isolation of the therapeutically important secondary glycosides, the finely ground material is moisturized and exposed to the enzymes at 30 – 37 °C until glucose is completely removed. Extraction procedures, usually followed by precipitation of tannic acid and related phenolic products with lead salts, afford a crude mixture of cardioactive compounds, which is further purified by chromatography and/or crystallization. For representative examples of isolation procedures, see Section 2.4.

Formerly, mixtures of glycosides or crude plant extracts were used in therapy; these have been replaced by chemically pure drugs today.

Total syntheses of cardiac steroids and their corresponding glycosides have been accomplished but are not used commercially. Chemical modification of the sugar part of natural glycosides has led to derivatives with improved pharmacokinetic properties, in particular better oral absorption. Efforts to achieve better differentiation of cardiotonic and cardiotoxic properties, that is, to obtain compounds with a wide safety margin, by chemical modification have not been successful.

2.3. Pharmacology and Clinical Therapy

2.3.1. Pharmacological Investigation [13], [28–30]

Experimental models for evaluating cardiotonic effects include the papillary muscles of cats or guinea pigs and isolated organs, such as the guinea pig auricle [32], [33]. These preparations do not contract spontaneously, but are stimulated through electrodes at a certain frequency. Contractility is determined by measuring the isometric contraction after the addition of cumulatively increasing doses of cardiac glycosides to the medium.

Other models are the perfused heart preparation of Langendorff and the heart–lung preparation [33]. These models resemble the intact animal more closely and provide more detailed information about therapeutic and toxic parameters as well as oxygen consumption in the presence and absence of cardiac glycosides.

Cardiotonic effects of glycosides in cultures of heart cells were observed as early as 1955. Since improved techniques for the observation and registration of single cells have become available, this method is gaining attention.

Inotropic effects in the intact, anesthetized animal (cat or dog) are evaluated under continued infusion by measuring *intracardiac pressure.* The maximum rate of pressure rise (dp/dt_{max}) in the left ventricle serves as an index for inotropy (Fig. 3). By monitoring the electrocardiogram one can determine both inotropy and the dose at which arrhythmias occur. Continued infusion finally leads to cardiac arrest (lethal dose). By measuring these parameters, the *therapeutic range,* that is the ratio between the dose that produces the therapeutic effect and the dose that causes toxic side effects, can be determined [34].

The lethal dose (LD) is determined by intravenous infusion until cardiac arrest either in anesthetized cats (method of Hatcher) or in anesthetized guinea pigs (methods of Knaffl-Lenz); this parameter has formerly been used for the assessment of cardiac glycosides. Currently, toxic parameters (Table 4) are employed mainly for the determination of intestinal absorption and duration of action. A common procedure for measuring intestinal absorption is

to administer a sublethal dose of the glycoside orally or intraduodenally and then to determine the supplementary intravenous dose needed to produce cardiac arrest. Duration of action can be determined in a similar way.

Figure 3. Schematic representation of the left ventricular pressure (A) and its derivative (B)
The maximum rate of pressure rise dp/dt_{max} in this case is 266 mbar/40 ms = 6650 mbar/s [31]

Table 4. Cardiotoxicity of some glycosides (intravenous administration, cat)

Glycoside	Lethal dose, mg/kg
Digitoxin [*71-63-6*]	0.32 – 0.42
Gitoxin [*4562-36-1*]	0.59 – 0.80
Oleandrin [*465-16-7*]	0.20
Digoxin [*20830-75-5*]	0.23 – 0.28
3‴-Acetyldigoxin [*5511-98-8*]	0.36 – 0.47
4‴-Acetyldigoxin [*5355-48-6*]	0.37 – 0.43
4‴-Methyldigoxin [*30685-43-9*]	0.33 – 0.38
k-Strophanthoside [*33279-57-1*]	0.13 – 0.19
Convallatoxin [*508-75-8*]	0.07 – 0.08
Cymarin [*508-77-0*]	0.11 – 0.13
Peruvoside [*1182-87-2*]	0.15
Ouabain [*11018-89-6*]	0.09 – 0.13
Proscillaridin [*466-06-8*]	0.16 – 0.18

2.3.2. Mode of Action [14], [35], [36]

The membrane-bound Na^+- and K^+-dependent adenosine triphosphatase (Na^+, K^+-ATPase) has been identified as the site of action of digitalis at the molecular level. Under physiological conditions this enzyme hydrolyzes adenosine triphosphate (ATP) to achieve the exchange of intracellular Na^+ for extracellular K^+ against concentration gradients. Cardiac glycosides bind to a specific receptor site of the enzyme at the external surface of the membrane-bound enzyme. Inhibition of the active transport system by glycosides leads to an increase in intracellular Na^+ and a decrease in intracellular K^+. The accumulation of Na^+ in the heart muscle cell is linked to an increased influx of Ca^{2+}, which is regulated by the Na^+/Ca^{2+} carrier system. As a consequence more Ca^{2+} is available for interaction with the myofibrils.

According to this hypothesis, supported by numerous investigators [37] inhibition of the enzyme must be basic to the inotropic action of cardiac glycosides. At higher digitalis concentrations the pump capacity is lowered and may eventually fall below the limit required to maintain ionic homeostasis. The resulting persistent increase in intracellular Na^+, combined with loss of K^+ and heavy uptake of Ca^{2+} from external sources, causes the symptoms of cardiac glycoside intoxication.

There is no contention that Na^+, K^+-ATPase is the binding site for glycosides or that inhibition of this enzyme is responsible for their toxicity; however, it is still controversial whether pump inhibition is causally related to the development of inotropy. Opponents of the Na^+, K^+-ATPase hypothesis stress the enormous difference between the concentration of $10^{-6} - 10^{-7}$ mol/L that is needed to produce an inotropic effect in isolated organs and the 100 – 1000 times lower therapeutically effective concentration of cardiac glycosides in humans. Assumption of significant contributions of extracardiac, neuronal effects that arise, e.g., from inhibition of neuronal Na^+, K^+-ATPases might possibly explain this discrepancy.

2.3.3. Pharmacokinetics [30], [38], [39]

Because of the narrow therapeutic range of cardiac glycosides, knowledge of their pharmacokinetic behavior is essential for safe therapy. Cardiac glycosides are very similar in their pharmacodynamic actions, but they vary considerably in their pharmacokinetic properties, according to their different lipophilicities. Such differences include absorption after oral application, onset of action, plasma protein binding, duration of action, rate of elimination, and mode of excretion.

Absorption. Treatment of congestive heart failure apart from emergencies requires continued medication; therefore, only orally active glycosides are used in therapy. Gastrointestinal absorption takes place predominantly in the small intestine and varies among different glycosides. Important parameters for absorption are (1) water solubility as a prerequisite for dissolution in the gastrointestinal tract and (2) high lipophilicity to facilitate rapid diffusion through the membrane of the intestinal mucosal wall. Polar molecules such as ouabain are very poorly absorbed and can only be administered intravenously, whereas the nonpolar digitoxin is taken up from the gastrointestinal tract nearly quantitatively.

The *absorption ratio* has been defined as the therapeutically effective fraction of the total amount of orally given drug. Variations in the rate and extent of dissolution of different commercially available digoxin tablets have been found to be responsible for widely differing serum levels of the drug (for bioavailability, see [40]). With the development of improved pharmaceutical preparations and of bioavailability specifications, the problem of variable absorption ratios has been solved.

The extent of *plasma protein binding* in the blood depends on the hydrophobicity of the glycoside. Nonpolar digitoxin is bound to the extent of more than 90 %, digoxin is bound to about 30 %, and ouabain shows less than 10 % binding.

Metabolism. Biotransformation also differs among the various glycosides according to their lipid solubilities. Hydrophobic digitoxin is metabolized extensively in the liver, but digoxin is only slightly degraded (about 10 %), and the polar ouabain is excreted unchanged. Metabolism of digitoxin in the liver occurs by successive cleavage of the three digitoxose molecules and is accompanied by hydroxylation at C-12 of the steroid. The very slow removal of the terminal digitoxose molecule accounts for the long duration of action.

Duration of Action. Digitalis glycosides and their metabolites are excreted mainly via the kidney. As a consequence elimination is slower in patients with renal insufficiency. This effect is particularly seen with digoxin and its semisynthetic derivatives. In contrast, excretion of digitoxin and proscillaridin is independent of renal function.

For practical therapy the duration of action is of great importance. The *decay ratio* defines the amount of the total body pool in percent that in the course of 24 h loses its effect on the heart because of inactivation and/or elimination. Alternatively, the *half-life* (the time required for a given blood level of the drug to decrease to 50 %) is commonly used to specify the duration of action of a particular glycoside.

The *oral maintenance dose* is the amount of glycoside that must be given daily to maintain a steady therapeutic level.

2.4. Clinically Important Cardiac Glycosides [41–43]

2.4.1. Glycosides with Long Duration of Action

Cardiac glycosides derived from digitoxigenin are characterized by a long duration of action, almost complete absorption from the gastrointestinal tract, and a very slow onset of action. Lanatoside A and acetyldigitoxin are both easily metabolized to digitoxin; they do not exhibit any advantages over digitoxin and are no longer important in therapy.

Digitoxin [*71-63-6*], 3β-[(*O*-2,6-dideoxy-β-D-ribo-hexopyranosyl-(1 $\rightarrow$ 4)-*O*-2,6-dideoxy-β-D-ribo-hexopyranosyl-(1 $\rightarrow$ 4)-2,6-dideoxy-β-D-ribo-hexopyranosyl)oxy]-14-hydroxy-4β,14β-card-20(22)-enolide (structure 3), $C_{41}H_{64}O_{13}$, M_r 764.92, *mp* 252 °C, $[\alpha]_D^{20} = +17°$ (chloroform : methanol 1 : 1), is isolated from *Digitalis purpurea* and purified [44–46]. Digitoxin is useful for maintenance therapy because its long half-life (5 – 9 days) provides a sustained therapeutic effect even if a dose is missed. For the same reason toxic reactions are not easy to manage. Elimination is independent of renal function.

Absorption ratio 90 – 100 %, decay ratio 7 %, effective dose level 2 mg, maintenance dose 0.15 mg.

Trade names: Crystodigin (Lilly), Digimerck (Merck).

Gitoxin, which can also be obtained from *Digitalis purpurea* and *D. lanata,* is not bioavailable because of its extreme insolubility in water and organic solvents. Prodrugs, such as pentaacetylgitoxin [47] and pentaformylgitoxin [48], are readily metabolized in humans to the cardioactive 16-acyl derivatives.

Pengitoxin [*7242-04-8*], pentaacetylgitoxin, $C_{51}H_{74}O_{19}$, M_r 991.13, *mp* 151 – 155 °C, $[\alpha]_D^{20} = +14°$ (pyridine); for synthesis see [49]. Absorption ratio 60 – 65 %, decay ratio 10 %, effective dose level 2.5 – 3 mg, maintenance dose 0.4 mg. Pengitoxin is comparable to digitoxin but is absorbed to a smaller extent.

Trade names: Pentagit (ASTA Medica AWD).

2.4.2. Glycosides with Medium Duration of Action

Digoxin and its derivatives are therapeutically the most useful and most widely used digitalis glycosides. Their pharmacokinetic properties are intermediate between the nonpolar, orally well-absorbed digitoxin with its long half-life and the polar, short-acting strophanthus glycosides.

Digoxin [*20830-75-5*] (structure Fig. 2), $C_{41}H_{64}O_{14}$, M_r 780.92, *mp* 265 °C, $[\alpha]_D^{20}$ +13.3° (pyridine), is isolated from *Digitalis lanata* [50]. Absorption ratio 70 %, decay ratio 20 %, effective dose level 2 mg, maintenance dose 0.5 mg.

Digoxin is regarded by most as the drug of choice for the treatment of congestive heart failure. The reasons are the very rapid onset of action (5 – 30 min after intravenous and 2 – 3 h after oral administration), the good absorption ratio, and, above all, the medium half-life which makes toxic reactions easier to manage. Digoxin can be administered either intravenously or orally, and the maintenance dose is thus easily established after emergency intravenous use. Digoxin is excreted mainly in the urine; in patients with impaired renal function, the half-life is prolonged.

Trade names: Digacin (Beiersdorf), Lanicor (Roche), Lanoxin (Glaxo Wellcome).

To improve the oral absorption of digoxin, a series of digoxin derivatives have been synthesized by acylation or methylation of the terminal digitoxose residue.

α-Acetyldigoxin [*5511-98-8*], 3‴-acetyldigoxin, $C_{43}H_{66}O_{15}$, M_r 823.0, *mp* 230 °C (decomp.), $[\alpha]_D^{20} = +21°$ (pyridine), is prepared from lanatoside C (Fig. 2) by enzymatic hydrolysis of the D-glucose unit [51] or from digoxin by reaction with triethylorthoacetate and subsequent partial hydrolysis of the orthoacetate [52]. Absorption ratio 80 %, decay ratio 20 %, maintenance dose 0.4 mg.

β-Acetyldigoxin [*5355-48-6*], 4‴-acetyldigoxin, $C_{43}H_{66}O_{15}$, M_r 823.0, *mp* 240 °C (decomp.), $[\alpha]_D^{20} = +31.5°$ (pyridine), is synthesized by selective acetylation using acetic anhydride in pyridine [53].

Trade names: Novodigal (Beiersdorf).

Medigoxin [*30685-43-9*], metildigoxin, β-methyldigoxin, 4‴-methyldigoxin, 16′-methyldigoxin, $C_{42}H_{66}O_{14}$, M_r 794.97, *mp* 226 – 229 °C, is made from digoxin by methylation with dimethyl sulfate in the presence of barium hydroxide and aluminum oxide [54]. Absorption ratio 95 %, decay ratio 22 %, maintenance dose 0.2 – 0.3 mg. Medigoxin is characterized by nearly complete absorption and a very rapid onset of action (5 – 20 min after oral administration).

Trade names: Lanitop (Roche).

2.4.3. Glycosides with Short Duration of Action

The strophanthus glycosides are characterized by a rapid onset and a very short duration of action. When toxic symptoms arise, they are relatively transient. Because of their high polarity, they are practically not absorbed when administered orally. Currently they are used only for intravenous therapy. The squill glycoside proscillaridin and its semisynthetic derivative meproscillarin combine the assets of the short duration of action of ouabain with satisfactory (proscillaridin) to good (meproscillarin) absorption. Cymarin is also orally active; it is derived from *k*-strophanthoside by enzymatic hydrolysis of two glucose units.

Digoxin: R^1, $R^2 = H$
3‴-Acetyldigoxin: $R^1 = COCH_3$, $R^2 = H$
4‴-Acetyldigoxin: $R^1 = H$, $R^2 = COCH_3$,
4‴-Methyldigoxin: $R^1 = H$, $R^2 = CH_3$,

Ouabain [*11018-89-6*], *g*-strophanthin, 3β-[(6-deoxy-α-L-mannopyranosyl)oxy]-1β,5,11α,14,19-pentahydroxy-5β,14β-card-20(22)-enolide octahydrate, $C_{29}H_{44}O_{12} \cdot 8\,H_2O$, M_r 728.78, *mp* 198 – 202 °C (decomp.), $[\alpha]_D^{20} = -30$ to $-33°$ (water); for its isolation, see [55]. Decay ratio 40 %, maintenance dose 0.25 mg (intravenous). Ouabain is used when rapid therapeutic benefit is required, especially in acute congestive heart failure.

Trade names: Ouabain-Nativelle (Nativelle, Wilcox), Strodival (Herbert).

Cymarin [*508-77-0*], *k*-strophanthin-α, $C_{30}H_{44}O_9$, M_r 548.65, *mp* 148 °C, $[\alpha]_D^{20} = +39°$ (methanol), is isolated from the seeds of *Strophanthus kombé* after enzymatic digestion [56]. Absorption ratio 33 %, decay ratio 40 %, maintenance dose 2.8 mg.

Proscillaridin [*466-06-8*], $C_{30}H_{42}O_8$, M_r 530.64, *mp* 227 – 230 °C, $[\alpha]_D^{20} = -93.5°$ (aqueous methanol), is isolated from *Scilla maritima* [57]. Absorption ratio 30 – 35 %, decay ratio 40 – 50 %, maintenance dose 1 – 1.5 mg. Because of its short duration of action, toxic symptoms after overdosage disappear within one day. Elimination is independent of renal function.

Trade names: Talusin (Knoll).

Meproscillarin [*33396-37-1*], proscillaridin-4′-methyl ether, $C_{31}H_{44}O_8$, M_r 544.66, *mp* 213 – 217 °C, $[\alpha]_D^{20} = -94°$ (methanol); for its synthesis, see ref. [58]. Absorption ratio 80 – 90 %, decay ratio 40 %, maintenance dose 0.5 – 0.75 mg. Meproscillarin and its metabolites are mainly eliminated by bilary secretion. The rapid elimination is not influenced by renal function. The bioavailability of meproscillarin is substantially improved compared to that of proscillaridin.

Trade names: Clift (Knoll).

3. Nonglycosidic Inotropic Agents

Because of the narrow therapeutic range and the side effects of digitalis glycosides, an intensive worldwide search for new positive inotropic agents that act by other mechanisms occurred over the past three decades. A hetereogeneous group of positive inotropic drugs were evaluated. Although these substances demonstrated improved hemodynamics and an improvement of symptoms in the short-term treatment of heart failure [59], [60], [61], [62], their use for long-term treatment has not been advocated due to a high incidence of adverse events and increased mortality that were observed in large clinical trials [63].

3.1. Sympathomimetics

Stimulation of β_1-adrenoreceptors, located at the extracellular side of the sarcolemma, results in increased production of cyclic adenosine monophosphate (cAMP) by stimulation of adenylate cyclase. Cyclic adenosine monophosphate then activates the slow inward Ca^{2+} channels, increasing the force of contraction, and accelerates the uptake of Ca^{2+} by the sarcoplasmic reticulum, decreasing the duration of contraction (relaxant effect) [64].

The clinical usefulness of the standard β-sympathomimetics such as epinephrine, norepinephrine, and isoproterenol is limited by their strong effects on heart rate and blood pressure. The more selective dopamine and dobutamine,

like the β-sympathomimetics mentioned above, are only effective by intravenous administration and have very short half-lives.

Dopamine. In patients with congestive heart failure, dopamine increases not only cardiac output, but also heart rate, pulmonary capillary wedge pressure, and systemic blood pressure. In addition, increased renal blood flow and consequent increased diuresis have been observed [65], [66].

Dopamine [*51-61-6*], 4-(2-aminoethyl)-1,2-benzenediol, $C_8H_{11}NO_2$, M_r 153.18, is made by demethylation of 3,4-dimethoxyphenethylamine [67]; the hydrochloride [*62-31-7*] melts at 241 °C (decomp.).

Trade names (hydrochloride): Catabon (Nikken), Dopamin (ASTA Medica AWD, Fresenius, Rhône-Poulenc Rorer), Dopamine (Abbott), Inovan (Kyowa Hakko), Intropin (American Critical Care, Du Pont).

Dobutamine, a derivative of dopamine, has comparable beneficial effects in the treatment of congestive heart failure. In contrast to dopamine, it reduces mean pulmonary wedge pressure and does not change blood pressure significantly or may even lower it [65].

Dobutamine is indicated in patients requiring short-term inotropic support. Because of its short half-life, which makes administration by infusion necessary, its use tends to be limited primarily to the treatment of cardiogenic shock.

Dobutamine [*34368-04-2*], (±)-4-[2-[3-(4-hydroxyphenyl)-1-methylpropyl]aminoethyl]-1,2-benzenediol, $C_{18}H_{23}NO_3$, M_r 301.38, is made by reductive condensation of 3,4-dimethoxyphenethylamine with 1-(4-methoxyphenyl)-3-butanone and demethylation [68]; the hydrochloride [*49745-95-1*] melts at 184 – 185 °C.

Trade names (hydrochloride): Dobutrex (Lilly).

Ibopamine [69], a prodrug form of *N*-methyldopamine, has been developed to meet the need for an orally effective positive inotropic agent for the treatment of chronic heart failure. Ibopamine is orally effective at daily doses of 100 – 350 mg with a duration of action of 4 – 5 h [70].

Ibopamine [*66195-31-1*], 4-[2-(methylamino)ethyl]benzene-1,2-diol diisobutyrate, $C_{17}H_{25}NO_4$, M_r 307.39, is made by reaction of epinine (deoxyepinephrine) with benzyl chloroformate, subsequent esterification with isobutanoyl chloride, and debenzylation [71].

Trade names (hydrochloride): Inopamil (Astra, Zambon), Scandine (Zambon).

Prenalterol is a partial β_1-agonist for mild to moderate congestive heart failure [74]. Prenalterol increases cardiac output and stroke work index; it decreases left ventricular filling pressure and systemic vascular resistance with a slight increase in heart rate and, therefore, favorably affects the balance between myocardial oxygen supply and demand. Long-term studies have revealed a decrease in responsiveness: after 3 – 6 months the effects of prenalterol were no longer significant [72]. This down-regulation of β-adrenoreceptors arises from a decreased sensitivity or a reduction in the number of β-adrenoreceptors after prolonged stimulation and seems to be a general problem.

Prenalterol [*57526-81-5*], (−)-(*S*)-4-[2-hydroxy-3-[(1-methylethyl) amino] propoxy] phenol, $C_{12}H_{19}NO_3$, M_r 225.29, *mp* 127 – 128 °C, for its synthesis, see [73]; hydrochloride [*61260-05-7*].

Trade names (hydrochloride): Hyprenan (Astra).

Xamoterol is another partial β_1-adrenoreceptor agonist used in the treatment of mild to moderate heart failure [74]. The drug is an agonist when sympathetic activity is low, and an antagonist when activity is high, reducing heart rate during exercise [75].

Xamoterol [*81801-12-9*], (±)-*N*-(2-[2-hydroxy-3-(4-hydroxyphenoxy)propyl]amino-ethyl)-4-morpholinecarboxamide, $C_{16}H_{25}N_3O_5$, M_r 339.39; the hydrogen fumarate [*69630-19-9*] melts at 168 – 169 °C. For synthesis, see [76].

Trade names (hydrogen fumarate): Corwin (Zeneca).

Denopamine is a selective partial β_1-adrenoreceptor agonist, developed by Tanabe Seiyaku as an orally active cardiostimulant [77].

Denopamine [*71771-90-9*], (*R*)-α-([2-(3,4-dimethoxyphenyl)ethylamino]methyl)-4-hydroxybenzenemethanol, $C_{18}H_{23}NO_4$, M_r 317.18; the hydrochloride [*64299-19-0*] melts at 130 – 140 °C. For synthesis, see [78].

Trade names: Denopamine, Kalgut (both Tanabe).

Dopexamine is a dopamine analogue for the treatment of acute and congestive heart failure [79–81].

Dopexaminel [*86197-47-9*], 4-[2-[[6-[(2-phenetyl)amino]hexyl]amino]ethyl]-1,2-benzenediol, $C_{22}H_{32}N_2O_2$, M_r 356.51, dihydrochloride [*38029-10-6*]. For synthesis, see [82]

Trade names: Dopexamine (Fujisawa); dihydrochloride: Dopacard (Rhône-Poulenc Rorer).

Pirbuterol and salbutamol belong to a group of β_2-adrenoreceptor agonists. They are used as selective bronchodilators (→ Antiasthmatic Agents), but they also enhance cardiac contractility. However, vasodilation rather than direct positive inotropic effects probably is the dominant mechanism of action [59], [60], [83].

Pirbuterol [*38677-81-5*], 2-hydroxymethyl-6-(1-hydroxy-2-*tert*-butylaminoethyl)pyridine-3-ol, $C_{12}H_{20}N_2O_3$, M_r 240.30; the dihydrochloride [*38029-10-6*] melts at 182 °C (decomp.) For synthesis, see [84].

Trade names (dihydrochloride): Exirel (Pfizer) (as bronchodilator).

3.2. Phosphodiesterase Inhibitors

Inhibition of phosphodiesterases, which are responsible for the degradation of cyclic adenosine monophosphate (cAMP), increases the concentration of cAMP and the Ca^{2+} level in the myocardial cell. The following inotropic agents have the common mechanism of selective inhibition of a cAMP-specific phosphodiesterase (PDE III) with a high affinity for cAMP, which is not stimulated by calmodulin [85]. These PDE III inhibitors have positive inotropic and vasodilatory properties. Phosphodiesterase inhibitors were found to be very effective in the treatment of acute cardiac failure [86–88] and although they looked very promising initially, they proved to be very disappointing later on. These compounds were found to increase overall mortality during long-term treatment in several extensive studies and they should not be used for that purpose [89–91].

Amrinone improves cardiac performance by enhancing cardiac contractility and by decreasing systemic vascular resistance and left ventricular filling pressure with little rise in heart

rate and slight decrease in blood pressure. Because of the high incidence of side effects, such as gastrointestinal disturbances and thrombocytopenia, the development of the oral form has ceased. The intravenous form has been introduced with strong restrictions on use [59], [60], [61], [86].

Amrinone [*60719-84-8*], 5-amino-(3,4′-bipyridine)-6(1*H*)one, $C_{10}H_9N_3O$, M_r 187.20, *mp* 294 – 297 °C (decomp.), is made by reaction of γ-picoline with dimethylformamide–$POCl_3$, condensation with cyanoacetamide, hydrolysis to the amide, and reaction with bromine – sodium hydroxide [87].

Trade names: Inocore, Wincoram (both Sanofi-Winthrop).

Milrinone has been shown to be effective in the treatment of severe heart failure[88]. Its mode of action is similar to amrinone, however, it is about 10 – 30 times more potent than amrinone. Milrinone shows a high level of side effects that limit its use to acute therapy.

Milrinone [*78415-72-2*], 1,6-dihydro-2-methyl-6-oxo(3,4′-bipyridine)-5-carbonitrile, $C_{12}H_9N_3O$, M_r 211.23, *mp* > 300 °C, is made by reaction of 1-(4-pyridine)propan-2-one with dimethylformamide dimethylacetal and condensation with cyanoacetamide [92].

Trade names: Corotrope, Primacor (both Sanofi-Winthorp).

Enoximone – administered intravenously or orally – markedly improves left ventricular function in patients with severe congestive heart failure [93]. Cardiac side effects and gastrointestinal disturbances may limit the clinical utility of enoximone [98].

Enoximone [*77671-31-9*], 4-methyl-3-(4-methylthiobenzoyl)imidazolin-2-one, $C_{12}H_{12}N_2O_2S$, M_r 248.16, *mp* 255 – 258 °C (decomp.), is made by Friedel-Crafts acylation of 3-methylimidazolin-2-one [94].

Trade names: Enoximone, Perfane (both Hoechst Marion Roussel).

3.3. Agents with Direct Stimulation of Adenylate Cyclase

Boforsin, a labdane diterpenoid, is able to stimulate the enzyme adenylate cyclase directly. This agent has positive inotropic, antihypertensive, and platelet aggregation inhibitory activity. Clinical trials with intravenous boforsin showed only a small increase in dp/dt_{max}, but strong increase in cardiac output, possibly as a result of its vasodilating properties [59], [60], [95], [96]. Development of boforsin as vasodilator and cardiotonic agent by Hoechst Marion Roussel has been discontinued.

Boforsin (forskolin) [*66575-29-9*], 5-acetoxy-3-ethenyldodecahydro-6, 10, 10b-trihydroxy-3, 4a, 7, 7, 10a-pentamethyl-[3*R*-(3α, 4aβ, 5β, 6β, 6aα, 10α, 10bα)]-1*H*-naphtho[2,1-*b*]pyran-1-one, $C_{22}H_{34}O_7$, M_r 410.49, melts at 230 – 232 °C; for its isolation, see [96].

3.4. Agents Acting on the Calcium Channels

Increasing the opening time of slow Ca^{2+} channels in heart muscle cells stimulates cardiac contractility by increasing the intracellular level of Ca^{2+}. This effect is seen with agents such as *BayK 8644* [97], which is closely related to

the calcium antagonists of the dihydropyridine type (→ Calcium Antagonists). Contraction of smooth muscle cells, producing a blood pressure increase, prevented the development of BayK 8644 as an inotropic agent. Pharmacological evaluation of its congener BAY-Y-5959 indicates ongoing interest in this mode of action [98].

1. General Survey

Cardiovascular diseases are among the most widespread of all illnesses and the most commonly occurring diseases in industrial countries. In the United States and Germany, 40 – 50 % of the annual deaths are caused by cardiovascular disorders [1], [2]. Their increase since 1945 is alarming. In some countries, such as the United States, Canada, Great Britain, and Scandinavia, this trend has reached its peak [3]. Results of the international Monica-Study (Monitoring of Trends and Determinants of Cardiovascular Disease) of the WHO show for 1985 – 1995 in most areas a distinct decrease in cardiovascular mortality, especially due to myocardial infarction by up to 50 % [4].

The treatment of these diseases plays a dominant role in medicine throughout the world, especially in the industrialized countries [5], [6], e.g., in the United States cardiovascular diseases accounted for $ 274 × 10^9 of medical expenses in 1998 [7].

In industrial nations the type of drug treatment practiced by physicians differs considerably. In Germany, for example, cardiac glycosides and antihypotensive drugs are used more frequently than in English speaking countries. Nevertheless, cardiovascular drug therapy plays a dominant role everywhere, both in terms of

10.1002/14356007.a05_289

numbers of prescriptions and expenditures for both in- and outpatients; it represents 10 – 15 % of the total costs for drugs in Germany [4], [5].

The principal function of the cardiovascular system is the exchange of materials among organs by the blood circulation. The heart, arteries, arterioles, capillaries, and veins together with the blood contained therein represent an integrated pumping and tubing system. Cardiovascular disorders can be caused by a disturbed single malfunction or an impaired interaction of multiple functions of this system. For instance, a decrease in the pumping capacity of the heart, dilatation of the blood vessels, or decrease in the quantity of blood being transported can all have the same effect: a decrease in blood pressure, which causes insufficient blood circulation. Morphological disorders, for example, by inflammation or degeneration of the heart or the blood vessels, or an abnormal blood composition (clotting factors, blood lipids) can occur as primary damage or as a result of functional disorders.

Historical Development. HARVEY discovered the blood circulation in 1628; on this basis the most important pathoanatomical, pathophysiological, and diagnostic discoveries were made over a period of about 300 years. The first systematic pharmacotherapeutic data were collected with cardiac glycosides (WITHERING, 1785); these drugs continue to be of central importance. After the development of structural and synthetic organic chemistry and experimental pharmacology in the middle of the 19th century other essential cardiovascular drugs became available:

1) Drugs for the regulation of heart action (quinidine 1918, procainamide 1953, ajmaline 1959)
2) Drugs for the treatment of angina pectoris (nitro compounds before 1900)
3) Drugs for the lowering of blood pressure (reserpine 1952, hydralazine 1953, chlorothiazide 1959, α-methyldopa 1960)

However, these drugs affected only symptoms of the diseases; some were weak or toxic and therefore had a limited effect. They were incapable of controlling the increasing cardiovascular morbidity and mortality. This stimulated cardiologists after 1945 to devote themselves to research on atherosclerosis, which was recognized as being the most important pathological condition associated with cardiovascular diseases. The importance of changes in the clotting system (thrombosis, platelet aggregation) and such metabolic disorders as diabetes mellitus, increase in lipid and uric acid concentrations in the blood, and obesity was recognized following the fundamental studies by VIRCHOW, v. ROKITANSKY, and ANITSCHKOW (ca. 1850 – 1900). Also, the necessity for such medical intervention as dietary and drug prophylaxis at an early stage was perceived [1]. This knowledge finally led to the extensive, long-term administration of the following types of drugs:

1) Blood lipid lowering (clofibrate 1963)
2) Blood glucose lowering (tolbutamide 1956, glibenclamide 1969)
3) Anticoagulatory (coumarin derivatives, phenprocoumon 1953)
4) Platelet aggregation inhibiting (acetylsalicylic acid 1970)

Since the 1950s progress has been made in the development of intensive cardiac electrotherapy and operative therapy. In addition, major clinical–pharmacological improvements resulted from development of drugs such as lidocaine (1969), methyldigoxin (1971), and isosorbide dinitrate (1959). Other milestones in cardiovascular drug treatment are the introduction of β-receptor blockers (propranolol 1964, numerous others since), calcium channel blockers (verapamil 1963), angiotensin converting enzyme (ACE) inhibitors (captopril 1969) and HMG-CoA reductase inhibitors (compactin 1976/78 and mevinolin 1980 – see Section 4.3.4). The β-receptor blockers receive increasing criticism because of their undesired side effects, principally effects on levels of blood lipids and blood glucose. On the other hand, some β-receptor blockers have been shown to be useful in chronic heart failure which had been considered a contraindication for these drugs for many years. Calcium channel blockers and ACE inhibitors are becoming increasingly important in the therapy of coronary heart disease, hypertension, cardiac arrhythmias, and other cardiovascular disorders, particularly since the introduction of verapamil, nifedipine and captopril in the United States in 1981.

2. Classification

There are complex pathoanatomical, pathophysiological, and pathogenetic relationships in the cardiovascular system, and very diverse drug effects result. Therefore, a classified survey of the biological and medical effects of cardiovascular drugs is given in this chapter. Cross references are made to other articles in this encyclopedia that treat cardiovascular or related drugs to facilitate the introduction to and orientation within this field.

Cardioactive drugs are agents that affect cardiac structures, including the coronary vessels. *Positive inotropic drugs* enhance contractile force and are primarily represented by the *cardiac glycosides* and other positive inotropic drugs (→ Cardiac Glycosides and Synthetic Cardiotonic Drugs) as well as sympathomimetics (→ Antihypotensives). *Antiarrhythmic Drugs* have a regulating effect on an abnormally slow, fast, or irregular heart action (→ Antiarrhythmic Drugs). *Coronary therapeutics* correct any imbalance between the amount of oxygen supplied to and consumed by the heart muscle by means of diverse mechanisms, some of which also affect the peripheral vessels (→ Coronary Therapeutics). This group also comprises the *β-receptor blocking drugs* and the *calcium channel blockers,* which are also treated in separate articles because of their importance and the number of other conditions in which they are indicated (→ Calcium Antagonists; → β-Receptor Blocking Agents); both types of drugs have an antiarrhythmic and an antihypertensive action.

Vasoactive drugs primarily induce functional or structural vascular changes. *Blood pressure affecting drugs* primarily affect peripheral arteries and arterioles by changing the tension of the vascular wall. *Antihypertensives* (→ Antihypertensives) decrease blood pressure by acting either directly on the vessel wall or indirectly by central nervous neurohormonal mediation; the same effect is also exerted by β-receptor blocking drugs, calcium channel blockers, and to a certain extent by diuretics. The decrease in blood pressure by diuretics may be caused partly by a decrease in blood volume. On the other hand, blood pressure can be increased by increasing the volume, e.g., with plasma or plasma substitutes (→ Blood; → Dextran). The medical value of antihypotensive therapy (→ Antihypotensives) by increasing the tension of the venous or arterial wall (sympathomimetics), especially by long-term oral administration, is regarded very differently from country to country.

Blood flow affecting drugs (see Chap. 6) are intended to normalize blood circulation in specific regions – in the arteries, the veins, and specific organs, e.g., in migraine treatment. Their effects can involve muscular mechanisms of the vessels like those of some antihypertensives, but some also improve the rheology of the blood, e.g., dextran or fibrinogenases from snake venom.

Finally, blood flow can be improved by preventing or dissolving blood clots (anticoagulants, fibrinolytics; → Blood, Chap. 2.2.3., and see Section 5). This effect leads to the therapeutic approaches that affect morphologically and structurally fixed changes in the vessel wall accompanying atherosclerosis (see Chap. 3); this therapy is more difficult but of increasing importance.

The complexity of the cardiovascular system and its disorders – often with multifarious etiology and increasing age-dependent multimorbidity – is the reason for the use of combination drugs in cardiovascular therapy in some areas and countries [4], [5].

3. Antiatherosclerotic Drugs (Survey)

The predominant cardiovascular diseases are directly or indirectly related to arteriosclerotic (atherosclerotic) vascular changes. Atherosclerosis is a principal cause of death, at least in the industrialized nations; in these countries the fight against atherosclerosis is a major issue [1]. Today, antiatherosclerotic strategy is based on a whole group of dietetic, behavioral, and medicinal methods, reflecting the complex etiology and pathogenesis of atherosclerosis.

Lipid Hypothesis. A number of discoveries led to the formulation of the lipid hypothesis [1], [2], [8–14]; these include:

1) Pathoanatomical findings (high concentrations of cholesterol, especially in the initial stages, beginning with soft "atheromas")

2) Random and systematic epidemiological observations (changes in incidence of atherosclerosis coinciding with changes in consumption of cholesterol and saturated fatty acids during and following times of war, Framingham Study)
3) Clinical findings (early atherosclerosis in certain types of familial hyperlipidemia)

The lipid hypothesis was subsequently modified by the concept of *risk factors*. According to this concept, increased levels of lipids in the blood are a decisive pathogenetic factor in coronary and peripheral atherosclerosis; these levels are also an indirect factor in apoplexy to the extent that preexisting coronary disease is a risk factor. Blood cholesterol has been demonstrated to be the most definite risk factor; this is further refined by differentiating among the cholesterol contents of various lipoproteins [13], [14], [22] (see also Chap. 4). Although the lipid hypothesis has been confirmed qualitatively and pathogenetically, the quantitative correlation between blood lipid levels and atherosclerosis is poorer than had been expected initially. Lipids have proven to be only one factor in a large group of causes; in specific cases a main cause can be assigned, e.g., cigarette smoking in peripheral angiopathy and hypertension in apoplexy. About half of the cases of coronary heart disease can be explained by such major risk factors as hyperlipidemia, hypertension, and cigarette smoking. Further factors include diabetes mellitus, hyperuricemia, and obesity [1], [4], [14].

The lipid hypothesis was the subject of much controversy mainly from the prophylactic – therapeutic point of view, in particular with regard to drug treatment. Early and some very extensive studies, e.g., the WHO Clofibrate Study [15], yielded only partially positive results on decrease in morbidity, e.g., by cardiac infarction, by the use of blood lipid lowering drugs. With regard to mortality and the benefit : expense : risk ratio, the results were disappointing both for primary prevention (symptom-free persons) and for secondary prevention (relapse prevention after myocardial infarction).

Therefore, further efforts focussed on practically oriented studies with individual drug therapy for *multiple risk factors* such as normalization of blood lipid levels, blood pressure, weight, or cigarette smoking. Several studies of this type demonstrated a significant reduction in mortality, but they also led to controversy about biometrics and interpretation, e.g., the so-called Mr. Fit Study (MRFIT, Multiple Risk Factor Intervention Trial) [16–19]. Also, the decrease in cardiovascular mortality observed in the United States and other countries can only be explained quantitatively by public and individual multifactor intervention on the part of physicians (treatment for infarction, hypertension, hyperlipidemia, changes in smoking habits, etc.) [2], [4].

Antiatherosclerotic Drugs. Such pathogenetic and prophylactic – therapeutic complexity makes the definition of antiatherosclerotic drugs difficult. This group of drugs comprises substances that primarily influence the atherogenic risk factors and secondary complications; it would include such drugs as antihypertensives and anticoagulants. However, the definition of antiatherosclerotic drugs should be more precisely limited to those drugs that intervene in the atherosclerotic vascular processes themselves. Today no such substances are available that have proven successful in clinical trials, in spite of claims to the contrary (e.g., the so-called chelate therapy for binding and mobilizing arterial calcium deposits). Calcium channel blockers and ACE inhibitors may be considered as promising antiatherosclerotic drugs by improving so-called "endothelial dysfunction" [20], [21].

Today blood lipid affecting drugs (see Chap. 4) are the nearest yet to true antiatherosclerotic drugs. As has been shown repeatedly by angiography and other tests, these drugs slow down or decrease atherosclerotic changes at least in cases of pronounced hyperlipidemia [1], [22], [23]. Of these early studies the Coronary Primary Prevention Trial [23] demonstrated a significant decrease (30 %) in the number of infarction deaths in 1900 men with familial hypercholesterolemia during seven years of treatment with a cholesterol-lowering ion-exchange resin (see Section 4.2.1). This study exerted considerable impact by setting standards for testing blood lipid lowering/antiatherosclerotic therapeutic and preventive (primary and secondary) drug regimes, e.g. administration of fibrates (gemfibrozil, Helsinki Heart Study 1987) [24], nicotinic acid, colestipol, lovastatin (SCOR, i.e., Regression of Coronary Atherosclerosis Study

of the University of California 1990) [25] and other statins [26–30] (see Section 4.3.4). All these studies not only proved the efficacy of specific drugs/drug regimes but – taken together – built up step by step overwhelming evidence in favor of the lipid hypothesis.

4. Blood Lipid Affecting Drugs

4.1. Introduction [31–35]

Abnormal, elevated concentrations of such blood lipids as cholesterol, cholesterol esters, triglycerides, and phospholipids are called *hyperlipidemia.* Such increased levels reflect quantitative disorders in the metabolism of lipids. Lipids do not circulate freely in the blood stream because they are insoluble in water. Instead, they are transported as part of protein complexes, the *lipoproteins* [1], [11]. Hyperlipidemias always correspond to changes in lipoprotein composition and pattern. Therefore, they are also more precisely called *hyperlipoproteinemias.*

Knowledge of the different types of lipoproteins, which are continuously synthesized, interconverted, and degraded, is essential for the understanding and treatment of hyperlipidemias. Lipoproteins are divided into five main groups according to their density, composition, and electrophoretic mobility (Table 1):

1) Chylomicrons carry mainly triglycerides.
2) *Very low density lipoproteins* (VLDL) also carry mainly triglycerides.
3) *Low density lipoproteins* (LDL) contain most of the plasma cholesterol and are considered to have a very high atherogenic potential. LDL are derived from metabolic breakdown of VLDL via IDL (see below).
4) *Intermediate density lipoproteins* (IDL) normally occur only in low concentration.
5) *High density lipoproteins* (HDL) appear to have an important function in the elimination of cholesterol from tissues. High levels of HDL have been linked with a reduced incidence of atherosclerosis, indicating a protective effect of this class of lipoproteins.

In addition, a specific lipoprotein called Lipoprotein (a) was found to be strongly associated with atherosclerosis [36], [37]. The blood level of this lipoprotein is genetically determined and so far, therapeutically hardly changeable.

Following a proposal of Fredrickson [11], hyperlipoproteinemias are classified in terms of abnormalities of lipoprotein patterns, comprising *primary* (genetically determined, familial) and *secondary* (symptomatic, e.g., diabetic) disorders (Table 2). Total plasma cholesterol and triglyceride concentrations reflect the composition of the lipoprotein classes that are affected in different types of hyperlipoproteinemias. Increased levels of plasma triglycerides are caused by chylomicrons or an increase in VLDL, whereas increased cholesterol levels are usually associated with increased concentrations of LDL, e.g., in type II.

Table 2. Types of hyperlipoproteinemias according to Fredrickson [11] (For abbreviations, see text)

Type	Lipoprotein class having increased blood levels
I	chylomicrons
II a	LDL
II b	LDL and VLDL
III	abnormal IDL
IV	VLDL
V	chylomicrons and VLDL

The discovery and study of the *LDL receptor* [38], a transmembrane glycoprotein, has increased understanding of the cellular basis of cholesterol homeostasis and the development of atherosclerosis. Apoprotein B-100, which is embedded in the large hydrophilic coat of LDL, is recognized by the LDL receptor on the cell; the lipoprotein is then bound to the LDL receptor and internalized into the cell by receptor-mediated endocytosis. In the cell LDL is eventually metabolized to yield cholesterol that regulates its intracellular concentration by a complex feedback system: cholesterol suppresses the enzyme 3-hydroxy-3-methyl glutaryl coenzyme A reductase (HMG-CoA reductase), thereby inhibiting its own synthesis; cholesterol also activates cholesterol acyltransferase so that any excess of cholesterol can be reesterified. Most important, cholesterol inhibits the synthesis of the LDL receptor, thereby preventing further LDL from entering the cell. The decrease in the number of LDL receptors slows down the rate at which LDL is removed from the circulation; consequently blood levels of atherogenic LDL

Table 1. Properties of plasma lipoproteins

Lipoproteins	Density, g/mL	Electrophoretic mobility ∗	Diameter, nm	Proteins, wt %	Cholesterol, wt %	Triglycerides, wt %
Chylomicrons	<0.95	–	100 – 1000	2	5	85
VLDL	0.95 – 1.006	pre-β	25 – 75	5 – 10	25	50
IDL	1.006 – 1.019	pre-β or β	25	15 – 20	35	10
LDL	1.019 – 1.063	β	20 – 25	20 – 25	45	10
HDL	1.063 – 1.210	α	5 – 12	40 – 55	20	10

∗ Electrophoretic mobilities are expressed in comparison to α- and β-globulins.

rise. The central role that LDL receptor deficiency plays in the development of atherosclerosis is documented in patients suffering from familial hypercholesterolemia (FH) [39].

There is some controversy as to what plasma cholesterol and triglyceride levels should be considered "normal" at different ages. However, there exists general agreement that cholesterol and triglyceride levels exceeding 200 mg/100 dL should give rise to thorough and differentiated diagnostic measures to identify or exclude an increased atherogenic risk pattern and decide upon the necessity of therapeutic intervention [40]. Dietary measures and weight normalization are the first choices in the treatment of elevated levels of plasma lipids. Drugs should be used only if these measures alone are unsuccessful or cannot be fulfilled consistently. Drug therapy (and drug development) should not be aimed only at decreasing total serum cholesterol and triglycerides. The goal is to reduce VLDL and especially LDL while keeping HDL at constant or, preferably, increased levels.

Drug Development. Screening for potential drugs [41], [42] is usually performed in rats or rabbits fed either a normal, controlled diet or a diet rich in cholesterol, triglycerides, or carbohydrates in order to induce hyperlipoproteinemias. Changes in plasma levels of cholesterol and triglycerides after repeated oral application are determined by standard analytical procedures. Assays allow differentiating between atherogenic VLDL and LDL and nonatherogenic HDL cholesterol [43]. For further details regarding animal models, see [44].

Toxicity studies are of paramount importance in the evaluation of potential drugs because of the preventive nature of antiatherosclerotic therapy. Because compounds that lower blood lipid levels are found quite frequently by the above methods, lack of toxicity is the true criterion for selecting appropriate compounds for drug development.

Mode of Action. The mechanisms of action of antilipidemic agents are not always fully elucidated. The drugs currently in use can be classified according to their main mode of action:

1) The first group comprises agents that affect *lipoprotein catabolism.* This group includes substances that interfere with intestinal absorption and reabsorption of lipids during enterohepatic circulation as well as compounds that directly enhance the rate of metabolic degradation.
2) The second group includes agents that affect *lipoprotein production*; they inhibit different stages of lipid synthesis and lipoprotein formation.

4.2. Drugs Affecting Lipoprotein Catabolism

4.2.1. Ion-Exchange Resins and Sitosterol

Several strongly basic anion-exchange resins have been found useful for the treatment of type II hyperlipoproteinemia; they remain completely unchanged in the gastrointestinal tract. They act by binding bile acids and preventing their enterohepatic circulation; in this way, hepatic conversion of cholesterol into bile acids is increased. In addition, the rate of LDL catabolism is accelerated. Sitosterol, which is absorbed to the extent of less than 5 %, has a structure very similar to that of cholesterol. It inhibits cholesterol absorption competitively.

Colestyramine [*11041-12-6*] is the chloride of a pharmaceutically acceptable form of the Dowex 1-X2resin with quaternary ammonium groups incorporated into a copolymer of styrene and divinylbenzene [45]. The average molecular mass of the insoluble resin is higher than 10^6.

Trade names: Quantalan, Questran (both Bristol-Myers Squibb).

Colestipol [*26658-42-4*] and its hydrochloride [*37296-80-3*] are copolymers of diethylenetriamine and 1-chloro-2,3-epoxypropane. For preparation, see [46].

Trade names (hydrochloride): Cholestabil (Fournier), Colestid (Pharmacia-Upjohn).

β-Sitosterol [*83-46-5*], 22,23-dihydrostigmasterol, $C_{29}H_{50}O$, M_r 414.69, *mp*140 °C, is isolated from natural sources, e.g., tall oil, wheat and rice germ oil [47]. Partial synthesis is from stigmasterol by selective hydrogenation [48].

Trade names: Cytellin (Lilly), Sito-Lande (Synthelabo).

4.2.2. Thyroxine Analogs

Thyroid hormones increase the catabolic rate of cholesterol and the elimination of LDL from the plasma, but LDL synthesis remains unchanged. Development of analogs has been aimed at achieving hypolipidemic activity without increasing the basal metabolic rate. Despite considerable success, calorigenic effects and cardiotoxicity are still a problem. In general, thyroxine analogs are only rarely used as lipid lowering drugs.

Dextrothyroxine [*51-49-0*], D-thyroxine, $C_{15}H_{11}I_4NO_4$, M_r 776.93, *mp* 237 °C. For synthesis, see [49]. The sodium salt [*137-53-1*] is mainly used in therapy.

Trade name (sodium salt): Dynothel (Henning).

4.3. Drugs Affecting Lipoprotein Synthesis

4.3.1. Nicotinic Acid and Derivatives

Nicotinic acid decreases the rate of synthesis of VLDL and LDL, increases LDL catabolism, and inhibits lipolysis. It is effective in type II to type V hyperlipoproteinemias. To minimize such side effects as flush or pruritus and to prolong the duration of action prodrugs and timed-release formulations have been developed. A new analog with significant advantages is acipimox which is effective at lower doses than nicotinic acid and encumbered with fewer side effects [50].

Nicotinic acid [*59-67-6*], pyridine-3-carboxylic acid, $C_6H_5NO_2$, M_r 123.11, *mp* 236.6 °C, is synthesized by the reaction of paraldehyde with ammonia to form 5-ethyl-2-methlpyridine [51] and subsequent oxidation with nitric acid [52], see also → Pyridine and Pyridine Derivatives.

Trade names: Niacin (numerous suppliers), Nicobid, Nicolar (both Rhône-Poulenc Rorer).

Xantinol nicotinate [*437-74-1*], pyridine-3-carboxylic acid and 3,7-dihydro-7-[2-hydroxy-3-[(2-hydroxyethyl)-methylamino]propyl]-1,3-dimethyl-1-*H*-purine-2,6-dione (1:1), $C_6H_5N_1O_2$ and $C_{19}H_{26}N_6O_6$, M_r 434.35, *mp* 180 °C. Preparation according to [53].

Trade name: Complamin (Smith Kline Beecham).

Inositol nicotinate [*6556-11-2*], myo-inositol hexa-3-pyridinecarboxylate, $C_{42}H_{30}N_6O_{12}$, M_r 810.73, *mp* 254 °C. For synthesis see [54].

Trade names: Hexanicit (Astra), Nicolip (Henning).

Acipimox [*51037-30-0*], 2-carboxy-5-methylpyrazine 4-oxide, $C_6H_6N_2O_3$, M_r 154.13, *mp* 177 – 180 °C; for synthesis see [55].

Trade names: Olbemox (Farmitalia Carlo Erba, Pharmacia-Upjohn), Olbetam (Farmitalia Carlo Erba).

4.3.2. Aryloxyisobutyric Acids, Derivatives, and Analogs

The class of compounds treated in this section comprises numerous substances with similar chemical, pharmacological, and clinical properties, which act primarily as antihypertriglyceridemic agents. The decrease in cholesterol levels is only moderate; therefore, these drugs are used mainly in type IIb, III, and type IV hyperlipoproteinemias. The oldest and still most widely used representative is clofibrate [56], which has been on the market since 1963. Mechanism of action of the fibrates is not yet completely understood. They increase the rate of VLDL catabolism by stimulating lipoprotein lipase activity and/or hepatic lipase activity [57], thereby lowering mainly plasma triglycerides. Other effects are inhibition of cholesterol synthesis and increase in excretion of neutral sterols [58].

Etofibrate combines the structural elements of nicotinic acid and clofibrate; therefore, it is used in all types of hyperlipidemias. The clofibrate analogs procetofene, bezafibrate, and gemfibrozil have only a small influence on the total cholesterol level, but they have been reported to lower selectively the LDL cholesterol level [25], [44], [59].

Clofibrate [*637-07-0*], 2-(4-chlorophenoxy)-2-methylpropanoic acidethyl ester, $C_{12}H_{15}ClO_3$, M_r 242.71, bp_{20} 148 – 150 °C, is synthesized by reaction of 4-chlorophenol with acetone and chloroform under alkaline conditions to form clofibric acid and subsequent esterification [60–62].

R = H: clofibric acidR = C_2H_5: clofibrate

Trade names: Atromid (American Home Products, Zeneca), Regelan (Zeneca).

Simfibrate [*14929-11-4*], 2-(4-chlorophenoxy)-2-methylpropanoic acid 1,3-propanediyl

ester, $C_{23}H_{26}Cl_2O_6$, M_r 469.36, *mp* 51 – 53 °C; for synthesis see [63].

Trade name: Cholesolvin (Yoshitomi).

Procetofene [*49562-28-9*], fenofibrate, 2-[4-(4-chlorobenzoyl)phenoxy]-2-methylpropanoic acid 1-methylethyl ester, $C_{20}H_{21}ClO_4$, M_r 360.84, *mp* 80 – 81 °C; for synthesis, see [64].

Trade name: Lipantyl (Fournier).

Bezafibrate [*41859-67-0*], 2-[4-[2-[(4-chloro-benzoyl)amino]ethyl]phenoxy]-2-methylpropanoic acid, $C_{19}H_{20}ClNO_4$, M_r 361.83, *mp* 155 – 156 °C; for synthesis, see [65].

Trade name: Cedur (Roche).

Gemfibrozil [*25812-30-0*], 5-(2,5-dimethylphenoxy)-2,2-dimethylpentanoic acid, $C_{15}H_{22}O_3$, M_r 250.35, *mp* 61 – 63 °C; for synthesis, see [66], [67].

Trade names: Gevilon, Lopid (both Warner-Lambert).

Etofibrate [*31637-97-5*] [*31637-97-5*], 2-hydroxyethyl nicotinate 2-(4-chlorophenoxy)-2-methylpropionate (ester), $C_{18}H_{18}ClNO_5$, M_r 363.79, *mp* 100 °C; for synthesis, see [68].

Trade name: Lipo-Merz (Merz).

Etofyllin clofibrate [*54504-70-0*], theofibrate, 2-(4-chlorophenoxy)-2-methylpropanoic acid 2-(1,2,3,6-tetrahydro-1,3-dimethyl-2,6-dioxo-7*H*-purin-7-yl) ethyl ester, $C_{19}H_{21}ClN_4O_5$, M_r 420.85, *mp* 133 – 135 °C; for synthesis, see [69].

Trade name: Duolip (Mepha, Merckle).

Ciprofibrate [*52214-84-3*], 2-[4-(2,2-dichlorocyclopropyl)phenoxy]-2-methyl-propanoic acid, $C_{13}H_{14}Cl_2O_3$, M_r 289.16, *mp* 114 – 116 °C; for synthesis, see [70].

Trade name: Lipanor (Sanofi).

4.3.3. Probucol

Probucol [*23288-49-5*], 4,4′-[(1-methylethylidene)bis(thio)]bis[2,6-bis(1,1-dimethylethyl)phenol], $C_{31}H_{48}O_2S_2$, M_r 516.84, *mp* 125 – 127 °C, lowers cholesterol by an as yet only partially elucidated mechanism, which involves inhibition of cholesterol synthesis and increase in the elimination of bile acids. Probucol decreases LDL and it has been reported also to have an antioxidative effect on LDL which may retard atherosclerotic progression [71]. In addition to decreasing LDL levels, probucol also lowers HDL cholesterol levels. This fact may require a careful evaluation of its usefulness in

antiatherosclerotic therapy. The oral absorption of probucol is low (5 – 10 %). For synthesis, see [72].

Trade names: Lorelco, Lurselle (both Hoechst Marion Roussel).

4.3.4. HMG-CoA Reductase Inhibitors

(CSE, Inhibitors, Statins). Compactin [73], [74] and mevinolin [75] are fungal metabolites isolated from the culture broths of *Penicillium citrinum* and *Aspergillus terreus,* respectively. Both compounds lower plasma cholesterol levels. They act by inhibiting β-hydroxy-β-methyl-glutaryl (HMG)-CoA-reductase, an enzyme that catalyzes an early rate-limiting step in cholesterol biosynthesis, i.e., reduction of HMG-CoA to mevalonic acid – the key substance for cholesterol biosynthesis. Following the demonstration of blood cholesterol reduction by this mechanism in humans [85], [86] intensive research and development led to introduction of lovastatin into therapy as the first drug of this class (1989). Since then, five additional compounds have been introduced, i.e., simva-, prava-, fluva-, atorva- and cerivastatin. Showing similar mechanism of action, these compounds differ in kinetics and metabolism (bioavailability <5 to 60 %). The most active compound so far is cerivastatin with effective daily dosages below 1 mg compared to 10 – 160 mg for the other compounds. The considerable medical and market success of the statins as the most widely used lipid lowering drugs is based not only on the intrinsic properties of these compounds. All statins have to a considerable extent contributed to the increase in knowledge regarding pathophysiology, clinic features and therapy of lipid disorders by producing more or less extended and well designed clinical trials for therapy and prevention in a wide area of indications: primary and secondary hyperlipoproteinemias, primary and secondary prevention, coronary heart disease, stroke, etc., with highly differentiated subgroups. Important studies are listed as follows: MARS = Monitored Atherosclerosis Regression Study (lovastatin) [28], 4S = Scandinavian Simvastatin Survival Study [27], WOS = West of Scotland Study (pravastatin) [26], CARE = Cholesterol and Recurrent Events Trial (pravastatin) [29], FLUENT = Fluvastatin Long-Term Extension Trial [30], AVERT = Atorvastin Versus Revascularization Treatments (1999, in progress).

Lovastatin [*75330-75-5*], (2*S*)-2-methylbutanoicacid (1*S*, 3*R*, 7*S*, 8*S*, 8*aR*)-1,2,3,7,8,8*a*-hexahydro-3,7-dimethyl-8-[2-[(2*R*,4*R*)-tetrahydro-4-hydroxy-6-oxo-2*H*-pyran-2-yl]-ethyl]-1-naphthalenyl ester, $C_{24}H_{36}O_5$, M_r 404.55, *mp* 174.5 °C. Lovastatin has been discovered and isolated as metabolite of *Monascus ruber*. [76] and from *Aspergillus terreus* [75].

Trade names: Mevacor, Mevinacor (both Merck & Co.).

Simvastatin [*79902-63-9*], 2,2-dimethylbutanoic acid (1*S*, 3*R*, 7*S*, 8*S*, 8*aR*)-1,2,3,7,8,8*a*-hexahydro-3,7-dimethyl-8-[2-[(2*R*,4*R*)-tetrahydro-4-hydroxy-6-oxo-2*H*-pyran-2-yl]-ethyl]-1-naphthalenyl ester, $C_{25}H_{38}O_5$, M_r 418.57, *mp* 135 – 138 °C. Simvastatin is a once-daily analogue of lovastatin. For synthesis see [77], [78].

Trade names: Denan (Boehringer Ingelheim), Lodales (Sanofi), Zocor (Dieckmann, Merck & Co).

Pravastatin [*81093-37-0*], (*βR*,*δR*,1*S*,2*S*,6*S*,8*aR*)-1,2,6,7,8,8*a*-hexahydro-*β*,*δ*,6-trihydroxy-2-methyl-8-[(2*S*)-2-methyl-1-oxobutoxy]-1-naphthaleneheptanoic acid, $C_{23}H_{36}O_7$, M_r 424.53. Pravastatin is the bioactive metabolite of mevastatin. For its preparation by microbial hydroxylation of mevastatin [79] at the 6-position see [80].

Sodium salt [*81131-70-6*], $C_{23}H_{35}O_7Na$, M_r 446.52.

Trade names (sodium salt): Pravachol, Pravasin (both Bristol-Myers Squibb), Mevalotin (Sankyo).

Fluvastatin [*93957-54-1*], (3*R*,5*S*,6*E*)-7-[3-(4-fluorophenyl)-1-(1-methylethyl)-1*H*-indol-2-yl]-3,5-dihydroxy-6-heptenoic acid, $C_{24}H_{26}FNO_4$, M_r 411.47, is a synthetic HMG-CoA reductase inhibitor, prepared according to [81].

Sodium salt [*93957-55-2*], $C_{24}H_{26}FNaNO_4$, M_r 434.46, *mp*194 – 197 °C.

Trade names (sodium salt): Canef, Cranoc (both Astra), Lescol (Novartis), Lochol (Tanabe Seiyaku).

Atorvastatin [*134523-00-5*], (*βR*,*δR*)-2-(4-fluorphenyl)-*β*, *δ*-dihydroxy-5-(1-methylethyl)-3-phenyl-4-[(phenylamino)carbonyl]-1*H*-pyrrole-1-heptanoic acid, $C_{33}H_{35}FN_2O_5$, M_r 558.65. For synthesis see [82].

Calcium salt [*134523-03-8*], (*βR*,*δR*)-2-(4-fluorphenyl)-*β*, *δ*-dihydroxy-5-(1-methylethyl)-3-phenyl-4-[(phenylamino)carbonyl]-1*H*-pyrrole-1-heptanoic acid calcium salt, $C_{66}H_{68}CaFN_4O_{10}$, M_r 1155.38.

Atorvastatin calcium is the only HMG-CoA reductase inhibitor approved for type III and IV lipid disorders.

Trade names (calcium salt): Lipitor (Warner-Lambert, Pfizer), Sortis (Warner-Lambert).

Cerivastatin [*145599-86-6*], (3*R*,5*S*,6*E*)-7-[4-(4-fluorophenyl)-5-methoxymethyl)-2,6-bis(1-methylethyl)-3-pyridinyl]-3,5-dihydroxy-6-heptenoicacid, $C_{26}H_{34}FNO_5$, M_r 459.55. For synthesis see [83].

Sodium salt [*143201-11-0*], $C_{26}H_{33}FNaO_5$, M_r 481.54. Preparation of the sodiumsalt [84].

Trade names (sodium salt): Baycol (Bayer, Smith Kline Beecham), Lipobay (Bayer), Zenas (Fournier).

5. Platelet Affecting Drugs

Platelet affecting drugs inhibit platelet aggregation and therefore prevent the formation of occluding platelet aggregates and thrombi. They are increasingly used in various thromboembolic cardiovascular diseases of mainly atherosclerotic origin, including myocardial infarction, stroke, transitory ischemic attacks and venous thrombosis. The effectivity of such therapy is confirmed [87]. A further indication is the prevention of ischemic complications in patients undergoing vascular surgery (e.g. percutaneous coronary revascularization). The therapy is based on the discovery that the aggregation of platelets – normally a physiologically important initial step in hemostasis maintaining the integrity of the vascular system – acquires

pathological significance when it becomes excessive, because it then can induce thrombotic occlusion and thus impairment of blood flow. To understand the mode of action of these agents, a knowledge of the very complex physiological and pathophysiological mechanisms that lead to platelet aggregation is necessary (see also → Blood, Chap. 2.2.3.).

5.1. Mechanisms of Platelet Aggregation

5.1.1. Physiological Situation

Under physiological conditions, when the vessel wall has been injured, the platelets immediately adhere to the exposed subendothelium, forming a monolayer. More platelets subsequently adhere to this monolayer to form an aggregate, which mechanically plugs the damaged site. This process is based on an activation of the platelets, which occurs in several stages: 1) an initial stickiness of the surface, 2) a shape-change, 3) aggregation, and 4) secretion. This activation can be triggered by numerous substances acting on specific receptors of the plasma membrane. The collagen of the subendothelium, which is exposed by vascular injuries, is of particular importance. Other important activation factors are the endogenous mediators released from activated platelets: adenosine diphosphate (ADP), the arachidonic acid metabolite thromboxane A_2 (TXA_2), and the platelet activating factor (PAF) [88]. Epinephrine (adrenaline) and norepinephrine (noradrenaline) probably play a special role; they are only weak aggregation inducers, but they lead to a massive intensification of the aggregation triggered by other inducers [89], [90].

Increased stickiness of the platelet surface is a prerequisite for adhesion and aggregation. The processes underlying this event involve a series of interactions between activated platelet receptors and adhesive proteins which are widely unknown in details [91]. The subsequent shape change consists of a transition from a disc shape to a globular form bearing pseudopodia-like protrusions, by which intercellular contact is facilitated. This shape-change is due to a contractile process mediated by actomyosin.

After the appearance of stickiness and shape-change, additional factors are necessary for aggregation to occur. These are a sufficient rate of blood flow (to bring about platelet contact) and sufficient amounts of calcium ions and fibrinogen in the plasma. A prerequisite to the aggregation process is finally the activation of glycoprotein IIb/IIIa receptors on the platelet surface which bind circulating fibrinogen (and other adhesive proteins) leading to the formation of fibrinogen bridges between the platelets [92].

Various substances are released during the aggregation process, either from storage in specific granules or through immediate biosynthesis. Storage compounds are: ADP, ATP, 5-hydroxytryptamine (5-HT), and calcium ions from the dense granules; and fibrinogen, platelet factor 4, β-thromboglobulin, and the platelet-derived growth factor (PDGF) from the α-granules. Immediately synthesized substances are the various arachidonic acid metabolites (in particular TXA_2) and the platelet activating factor (PAF).

The released substances induce a further avalanche-like increase in platelet aggregation (by ADP and TXA_2), a vascular contraction (by TXA_2 and 5-HT), which creates conditions of flow dynamics needed for the preservation of the platelet aggregate, and finally a promotion of blood clotting (by fibrinogen and platelet factor 4), which stabilizes the aggregate by fibrin precipitation and changes it into a thrombus. An integral part of this stabilization process is the contraction of actomyosin, which causes not only the secretion, but also the subsequent retraction of the clot.

An essential link between receptor stimulation and platelet reaction is the increase in the free calcium ion concentration in the platelets by release from intracellular stores and by inflow from extracellular space. The hydrolysis of inositol phospholipids in the cell membrane, in particular the catalytic formation of inositol 1,4,5-triphosphate (via phospholipase C), which mobilizes Ca^{2+} from intracellular stores, plays a central role in the increase of cytoplasmic Ca^{2+} concentration [93–96]. In addition, the cytoplasmic calcium ion concentration is increased by the influx of extracellular calcium ions into the cytoplasma. These processes can be reversed by various mechanisms, which finally restore the basal calcium ion concentration. Thus, the calcium ion-triggered platelet homeostasis can be regulated by intracellular cyclic 3′,5′-adenosine monophosphate (cAMP) which arises from ATP

by the action of adenylate cyclase. Activation of this enzyme (through different prostaglandins, among others) leads to an increase of the cAMP level, and thus to a sequestration of calcium ions within the dense tubular system [97–99].

Platelet activation is accompanied by a stimulation of lipid metabolism in the platelet membrane; the products of this process promote aggregation, see Figure 1. In addition to the breakdown of inositol phospholipids mentioned in the preceding paragraph the following processes also occur: formation of ether lipids (platelet activating factor; PAF) from choline alkyl ether [100] and liberation of arachidonic acid from phosphatidylethanolamine and phosphatidylcholine.

Arachidonic acid undergoes further changes [101], [102]. It is transformed by cyclooxygenase into the cyclic prostaglandin endoperoxides G_2 and H_2 (PGG_2 and PGH_2), which are further transformed into the extraordinarily potent aggregation inducer thromboxane A_2 (TXA_2; half-life 30 s) through the action of thromboxane synthetase. The manner in which the arachidonic acid metabolites 12-L-hydroxyperoxy- and 12-L-hydroxy-5,8,10,14-eicosatetraenoic acid (HPETE/HETE) formed by the action of lipoxygenase act on the platelets is not yet fully understood.

The importance of the arachidonic acid metabolites for platelet physiology and pathophysiology has gained a new aspect with the discovery of prostaglandin I_2 (PGI_2), or prostacyclin, in the vessel wall, particularly in the endothelial layer [103]. PGI_2 is a short-lived substance ($t_{1/2} = 2$ min) with powerful antiaggregatory and vasodilatory actions. Its action opposes that of TXA_2, which possesses both proaggregatory and strong vasoconstrictor properties. According to VANE's hypothesis, under normal conditions the formation of PGI_2 protects the intact vascular wall from any activation and aggregation of platelets by antagonizing TXA_2. However, injury of the vessel wall with loss of endothelium leads to a deficiency in PGI_2, with consequent displacement of equilibrium between pro- and antiaggregatory forces; this then results in platelet activation and thrombus formation under the influence of TXA_2.

5.1.2. Pathophysiological Situation

The pathophysiologically relevant formation of occluding platelet aggregates and thrombi occurs mainly at the site of chronic vascular wall alterations associated with atherosclerosis. These focal alterations start from damage to the endothelial cell layer of arteries, the "early lesions of the intima". This damage is caused by unknown mechanisms through such risk factors as overweight, hyperlipidemia, hypertension, and smoking. As a reaction, platelet accumulation as a rather early event and increased growth of smooth muscle cells occur, which results in a thickening of the vessel wall and thus narrowing of the vessel lumen. The process is reversible up to this point. However, if there is an elevated blood lipid level (hyperlipidemia), the smooth muscle cells will increasingly incorporate fat and eventually die. A necrosis of the fat-rich vessel wall, the irreversible *atherosclerotic plaque*, is the final result. Lesion of the intima as well as plaque formation initiate platelet activation and thereby induce thrombus formation.

Platelet aggregation is to be regarded as an essential pathogenic factor in the development of the atherosclerotic process [104]. According to experimental evidence, the *platelet-derived growth factor* (PDGF) plays an essential role in atherosclerosis. PDGF is a cationic protein with a molecular mass of about 30 000, liberated in the course of the release reaction; it is characterized by its strong stimulating action on the proliferation of arterial smooth muscle cells and fibroblasts in tissue cultures [105]. Whether such an action also takes place in vivo is as yet hypothetical. However, the release of PDGF may be the mechanism by which the atherosclerotic process is perpetuated: in a vicious circle PDGF liberation leads to progression of vessel wall alterations, inducing further platelet aggregation and renewed PDGF liberation. Additionally, the discovered macrophage-derived growth factor, which appears to be different from PDGF, may also play a role in atherogenesis [106], [107].

According to experimental studies on animals and clinical investigations, platelet affecting drugs can markedly reduce the proliferation of smooth muscle cells and the formation of preatherosclerotic and atherosclerotic lesions in vivo [106–109].

Figure 1. Pathways of lipid metabolism in activated platelets
(For abbreviations, see text)

In many cardiovascular diseases, there is an increased tendency for platelets to aggregate, and spontaneous formation of aggregates in the blood is observed. The causes of this effect are still rather obscure, but they are possibly linked to hyperlipidemia and an increased plasma level of catecholamines [110–114].

The significant *vasoconstrictor action* of the aggregators TXA_2 and 5-HT released from the platelets alone is probably of pathogenetic significance. This effect may participate in the development of circulatory shock, myocardial ischemia, and sudden death [115–117].

The pathophysiological significance of platelets is strongest in the arterial vascular bed because of the conditions of flow dynamics existing there and the positive correlation between blood flow rate and aggregation [118]. Consequently, in the venous vascular bed, platelet aggregation is less important in the development of thrombosis than clotting factors, but antiplatelet therapy reduced significantly the risk of deep venous thrombosis and pulmonary embolism [87].

5.2. Testing of Platelet Function

Platelet function is tested for clinical or experimental reasons preferably in vitro by means of platelet aggregation because good quantitative and reproducible methods exist [119]. For this purpose platelet-rich plasma (PRP) obtained from venous blood is used and aggregation is induced by the addition of such compounds as ADP, collagen, thrombin, PAF, epinephrine, or 5-HT. In addition, spontaneous aggregation can be studied [120]. Aggregation is manifested optically by clarification of the initially turbid plasma. This clarification can be followed photometrically in an aggregometer; as an index the aggregation rate, its maximum, or the area under the aggregation curve is used. In addition, whole blood aggregations can be measured by impedance technique [121]. Platelet affecting drugs can be studied either after addition in vitro or they are administered to humans or animals and aggregation is determined in plasma or blood samples obtained at different times after the administration. The extent of the aggregation inhibition is evaluated by comparison with a control group [122].

By suitably modified techniques the initial shape-change of the platelets and the secretion (e.g., of ATP) can also be studied [123]. The adhesiveness of platelets is determined, for example, by measuring the decrease in platelet count after running platelet-rich plasma through a tube filled with glass beads.

For special experimental investigations washed or gel-filtered platelets are used; in this case, the plasma is replaced by electrolyte solutions [124].

Several methods are available for the study of aggregation or its inhibition in vivo, e.g., the induction of thrombocytopenia by intravenous injection of an inducer, such as ADP, to produce intravascular aggregation; the subsequent decrease in platelet count with time is plotted to establish the kinetics of the process [125].

Finally, for the determination of an antithrombotic action, the vessel wall can be damaged by several means or an artificial arterio-arterial or arterio-venous shunt is inserted and thrombus formation can be followed gravimetrically, by radioactive markers, histologically or by measuring the flow reduction [126–131].

5.3. Specific Platelet Affecting Drugs

5.3.1. Inhibitors of Prostaglandin Synthesis [132]

Thromboxane A_2 (TXA_2) is one of the most active mediators of aggregation (see Section 5.1). The aggregation induced by low concentrations of collagen depends on TXA_2 formation, whereas the initial adhesion and the related release reaction occur without participation of TXA_2. Platelet aggregation caused by thrombin and PAF, as well as the sensitization of the platelets by epinephrine, are also independent of TXA_2. Therefore, substances that inhibit prostaglandin synthesis can prevent only one of the ways by which platelets are able to mediate thrombogenesis.

Prostaglandin synthesis inhibitors are classified into two categories:

1) *Cyclooxygenase inhibitors* (acetylsalicylic acid/aspirin)
2) *Thromboxane synthase inhibitors* (no drug on the market)

5.3.1.1. Cyclooxygenase Inhibitors

Aspirin irreversibly inhibits platelet cyclooxygenase through acetylation. Because platelets are unable to synthesize proteins, the inhibitory effect persists until the end of the life span of the platelets, i.e., for about 7 days [133]. The cyclooxygenase inhibition is not tissue-specific for platelets but specificity can be achieved by low oral doses and controlled release formulations of aspirin to restrict the drug – platelet interaction to the presystemic, portal circulation [134].

Cyclooxygenase inhibitors prevent not only the formation of TXA_2, but also that of prostaglandin endoperoxides, e.g., PGH_2 and PGD_2 (Fig. 1), which have partly pro-, partly antiaggregatory potential, as well as that of PGI_2 in the vessel wall. The latter action is undesirable because of the antithrombotic properties of PGI_2 (see page 17). In the aortic intima, however, cyclooxygenase is about 60 – 250 times less sensitive to aspirin than in platelets; in addition, the inhibition is reversible there [135–137]. Although a thrombogenic action has not been demonstrated for higher doses of aspirin, lower doses are recommended in order to limit the inhibition of PGI_2 synthesis (325 mg/day or as low as 0.45 mg kg^{-1} day^{-1}) [138–140].

Clinical trials showed that the use of aspirin in survivors of myocardial infarction reduces the risk of reinfarction and death significantly [87], [141]. It is also effective in certain forms of cerebral vascular disease, however, the optimal dosage is less clear [142], [87]. Furthermore aspirin is used at present as a standard treatment in patients undergoing coronary revascularization [87], [143]. Aspirin as an antiplatelet drug is most widely administered in a medium dose of 75 – 325 mg/d which reduces the risk of gastrointestinal intolerance or bleeding and results in an acceptable risk – benefit ratio for most patients. The gastrointestinal intolerance can be further diminished by using enteric-coated formulations [143].

From the mode of action it is obvious that aspirin is not an optimal antiplatelet drug, especially in the indication of coronary revascularization, since important pathways in platelet activation which are of relevance in such patients, e.g., activation by ADP and thrombin, expression of GP IIb/IIIa receptors, are not affected. The efficacy of antiplatelet therapy can therefore be improved if aspirin is combined with drugs which interfere with the activation processes mentioned.

Acetylsalicylic acid [*50-78-2*], aspirin, 2-(acetyloxy)benzoic acid, salicylicacid acetate, is described in more detail under → Salicylic Acid.

5.3.1.2. Thromboxane Synthase Inhibitors

The undesirable effect of cyclooxygenase inhibitors on prostacyclin (PGI_2) formation has stimulated the development of thromboxane synthase inhibiting drugs. These substances selectively inhibit the transformation of endoperoxides to TXA_2; in this manner they shift the metabolism of the endoperoxides toward the formation of, e.g., PGH_2 and PGD_2 (in platelets, Fig. 1), and PGI_2 (in endothelial cells). It was subsequently shown that the persisting formation of the proaggregatory PGH_2 is of relevance for aggregation [144], but can be inhibited by TXA_2 receptor antagonists. Therefore, some expectations were directed to ridogrel, a potent inhibitor of the TXA_2 synthase that also possesses TXA_2/prostaglandin endoperoxide receptor blocking properties [145]. However, ridogrel was not superior to aspirin in patients with myocardial infarction after thrombolysis therapy in preventing early phase rethrombosis, but might be more effective in preventing new ischemic events [146]. The missing clear superiority of ridogrel to aspirin might be explained by different mechanisms, e.g., an insufficient capacity of atherosclerotic arteries to produce prostacyclin. More controlled prospective clinical trials are required to assess the therapeutic value of such substances especially in combination with aspirin.

Ridogrel [*110140-89-1*], R-68070, (*E*)-5-[[[3-pyridinyl[3-(trifluoromethyl)phenyl] methylene]amino]oxy]pentanoic acid, $C_{18}H_{17}F_3N_2O_3$, M_r 366.34, *mp* 70.3 °C; for synthesis, see [147].

5.3.2. Substances Influencing Cyclic 3′,5′-Adenosine Monophosphate

An increase in cyclic adenosine monophosphate (cAMP) prevents the initial shape change of the platelets, their adhesion to surfaces, the aggregation, and the release reaction, regardless of the type of stimulator. As a consequence of this broad activity pattern, substances influencing cAMP are of potential therapeutic interest.

The concentration of cAMP in the platelets can be increased (1) by stimulation of adenylate cyclase, which is responsible for the transformation of ATP into cAMP, or (2) by inhibition of cAMP-phosphodiesterase, which catalyzes the breakdown of cAMP to AMP (Fig. 2). The adenylate cyclase is stimulated via different receptors by prostacyclin (PGI_2) and the less potent PGD_2. Papaverine and dipyridamole inhibit cAMP-phosphodiesterase. Such inhibitors reinforce the action of PGI_2 and other adenylate cyclase activators; this reinforcement is generally obtained at lower doses than those that are necessary for inhibition of aggregation. Prostacyclin (PGI_2) and dipyridamole are clinically established as platelet aggregation inhibitors.

Figure 2. Mechanisms influencing the concentration of cAMP in platelets

Prostacyclin/Epoprostenol. At present prostacyclin (PGI_2) is the most active platelet aggregation inhibitor; the ADP-induced aggregation is inhibited by 50 % at a plasma concentration of 0.5 ng/L [148]. In addition, PGI_2 causes, both in humans and in animals, a systemic vasodilation with dose-dependent blood

pressure lowering, accompanied by an increase in heart rate; furthermore, a stabilization of lysosomes has been shown. The effects of PGI_2 are receptor -mediated and indications exist that these receptors may become down-regulated if there is a significant increase in PGI_2 production (e.g., acute myocardial infarction, unstable angina) [149], [150]. Decreased sensitivity of human platelets to PGI_2 also occurred during long-term intraarterial PGI_2 infusion in patients with peripheral vascular disease [151]. Prostacyclin has a very short biological half-life and must be administered as a continuous intravenous infusion. In humans, flush and, in most cases, headache develop, which disappear after the infusion is interrupted or slowed down [152]. No encouraging results were obtained with PGI_2 in a randomized, double-blind, placebo-controlled trial in patients undergoing percutaneous coronary revascularization. The drug was unable to inhibit platelet aggregation and to prevent restenosis [153].

Epoprostenol [*35121-78-9*], PGI_2, prostacyclin, 5-[(1*S*,3*Z*,5*R*,6*R*,7*R*)-7-hydroxy-6-[(1*E*,3*S*)-3-hydroxy-1-octenyl]-2-oxabicyclo[3.3.0]-oct-3-ylidene]pentanoic acid, (5*Z*,9α,11α,13*E*,15*S*)-6,9-epoxy-11,15-dihydroxyprosta-5,13-dien-1-oic acid, $C_{20}H_{32}O_5$, M_r 352.48, is unstable in aqueous solution [154]: its half-life at 37 °C is 2 min [155]; the monosodium salt [*61849-14-7*] is stable as a solid and insolution [156].

Prostacyclin is synthesized from prostaglandin $F_{2\alpha}$ systems [156–161].

Trade name monosodium salt: Flolan (Glaxo Wellcome).

Chemically stable PGI_2 derivatives such as carbacyclin [162] and iloprost [163] are easier to handle than prostacyclin. Carbacyclin [*69552-46-1*] has the same pharmacological profile as PGI_2 but only ca. 3 % of its activity. Iloprost is equipotent to PGI_2 with reference to platelet activity in vitro, but possibly superior to it on the basis of a reduced blood pressure lowering activity. In an experimental study in dogs iloprost was uneffective to prevent reocclusion of coronary arteries after thrombosis due to electrical injury and thrombolysis [164]. Until now there is no definite evidence that PGI_2 derivatives might be of clinical value as antithrombotics or as adjunct to aspirin. The development of carbacyclin has been discontinued and iloprost and other PGI_2 derivatives are at present used as blood flow increasing drugs.

Iloprost [*78919-13-8*], ciloprost, 5-[(1*S*,3*E*,5*S*,6*R*,7*R*)-7-hydroxy-6-[(1*E*,3*S*,4*RS*)-3-hydroxy-4-methyl-1-octen-6-ynyl]bicyclo[3.3.0]oct-3-ylidene]pentanoic acid, $C_{22}H_{32}O_4$, M_r 360.50; for synthesis, see [165–167].

Trade names: Endoprost, Ilomedin, Ilomedine (all Schering).

Dipyridamole. Dipyridamole, originally introduced as a coronary vasodilator, has an antithrombotic effect in animals [168]. The inhibition of platelet aggregation in vitro using platelet-rich plasma is weak and requires high concentrations [169]; a strong antiaggregatory action is nevertheless found when the test is carried out on whole blood [170], [171]. In whole blood the drug probably acts by increasing the plasma concentration of adenosine because it inhibits the re-uptake of adenosine by red blood cells. Adenosine itself stimulates adenylate cyclase via an external adenosine receptor, thereby causing an increase of cAMP. This effect is enhanced by an inhibition of platelet cAMP phosphodiesterase. Dipyridamole reduces the size of experimentally induced myocardial infarction [172]. Platelet adhesion to the subendothelium is prevented by dipyridamole in animals under experimental conditions [173], [174]. Evidence

exists for both a protective and a promoting action in experimentally induced atherosclerosis [175], [176].

Inhibition of thrombus formation by dipyridamole has been repeatedly demonstrated in humans. The superiority of a combination of dipyridamole and aspirin compared with aspirin in humans has been demonstrated in multicenter studies on the protective action on myocardial reinfarction [177] and on cerebrovascular thrombosis [178].

Dipyridamole [*58-32-2*], 2,2′,2″,2‴-[(4,8-di-1-piperidinylpyrimido[5,4-*d*]pyrimidine-2,6-diyl)dinitrilo]tetraethanol, $C_{24}H_{40}N_8O_4$, M_r 504.64, *mp* 163 – 165 °C, can be obtained from 2,4,6,8-tetrahydroxypyrimido[5,4-*d*]pyrimidine [179]:

For another route to dipyridamole, see [180].

Trade names: Agilease (Isei), Anginal (Yamanouchi), Cleridium (Marcofina), Coronarine (Negma), Corosan (Farmacologico Milanese), Coroxin (Malesci), Curantyl (Berlin-Chemie), Novodil (OFF), Perkod (Lab. Biogalénique), Persantin (Boehringer Ingelheim), Persantine (Boehringer Ingelheim); in combination with acetylsalicylic acid as Asasantin (Boehringer Ingelheim).

5.3.3. Inhibition of Platelet-Specific Agonist–Receptor Interaction

The platelets are activated by substances that interact with specific receptors in the plasma membrane. The inhibition of this interaction limits activation. Such a mechanism is apparently responsible for the effect of ticlopidine and the thromboxane receptor antagonists.

Ticlopidine. Ticlopidine is a long-acting inhibitor of platelet aggregation; all types of aggregation are inhibited [181–183]. The action of ticlopidine appears with a delay of 24 – 48 h and persists according to investigations in rats up to the end of the life span of the platelets (the half-life is about 2 days). Ticlopidine appears to change the platelet membrane irreversibly so that the binding of ADP and fibrinogen is greatly reduced. This effect is independent of the prostaglandin synthesis and the cAMP level. Furthermore, the substance has no influence on the formation of PGI_2 in the vessel wall. It prevents the proliferation of the intima, which occurs after experimental removal of the endothelium in the rabbit aorta [184]. The activity of the substance on platelet aggregation and adhesion has been demonstrated in humans [185], [186]; the maximum activity appears only after several days of administration. The effectivity of ticlopidine for the secondary prevention of stroke was shown [187]. However, in a ticlopidine aspirin stroke study ticlopidine was only slightly more effective than aspirin in reducing the incidence of stroke and death (17 versus 19 %) [188].

In some patients a change in the white blood cell count (granulopenia) was found as a side effect; the substance is therefore preferentially used in patients with intolerance to aspirin.

Ticlopidine [*55142-85-3*], 5-[(2-chlorophenyl)methyl]-4,5,6,7-tetrahydrothieno[3,2-*c*]pyridine, $C_{14}H_{14}ClNS$, M_r 263.79; hydrochloride [*53885-35-1*], *mp* 190 °C (decomp.), can be synthesized from thieno[3,2-*c*]pyridine [189]:

(see a: [190])

According to another method, ticlopidine is obtained by reacting 4,5,6,7-tetrahydrothieno-[3,2-*c*]pyridine with 2-chlorobenzyl chloride in the presence of potassium carbonate [189, b], [191]:

(see a: [190, b], [191], [192])

Another route leading to ticlopidine is shown in the following scheme [193]:

For further syntheses of ticlopidine, see [190, b], [194], [195].

Trade names (hydrochloride): Anagregal (Gentili), Antigreg (Piam), Aplaket (Rottapharm), Clox (Caber), Fluilast (Boniscontro e Gazzone), Klodin (Savio I.B.N.), Opteron (Therabel Pharma), Panaldine (Daiichi Seiyaku), Parsilid (Crinos), Ticlid (Sanofi Winthrop, Roche), Ticlopidina Dorom (Dorom), Tiklid (Sanofi Winthrop), Tiklyd (Sanofi Winthrop).

Clopidogrel, chemically related to ticlopidine, similarly inhibits the ADP receptor by selective binding, affects fibrinogen binding with about sixfold higher potency and additionally inhibits thromboxane mediated aggregation [196], [197]. After oral administration the substance is rapidly absorbed and undergoes metabolic activation in the liver. In experimental studies clopidogrel reduced the formation of both arterial and venous thrombi and was more effective than aspirin to prevent reocclusion after thrombolysis [198], [199]. However, in a large multicenter study (CAPRIE) in patients at risk of ischemic stroke, myocardial infarction, or vascular death, clopidogrel was only of slightly greater benefit than aspirin [200].

Clopidogrel [*113665-84-2*], methyl (+)-(*S*)-α-(2-chlorophenyl)-6,7-dihydrothieno[3,2-*c*]-pyridine-5(4*H*)-acetate, $C_{16}H_{16}ClNO_2S$, M_r 321.83; hydrogen sulfate [*135046-48-9*], *mp* 184 °C, $[\alpha]_D^{20}$ +55.10° (c = 1.891, methanol), can be prepared by condensing 4,5,6,7-tetrahydrothienol[3,2-*c*]pyridine with racemic methyl α-chloro-(2-chlorophenyl)acetate in the presence of potassium carbonate [192], [201] and optical resolution of the product obtained [202]:

(see a: [190, b], [192], [191]; b: [203])

For another route to the product from the condensation step of the synthesis shown above, see [204].

Alternatively, clopidogrel can be obtained as shown below [205]:

(see a: [193]; b:[192], [191], [207], [208]; c: [206]; d: [204])

For further possibilities to synthesize clopidogrel see [205].

Trade names (hydrogen sulfate): Iscover (Bristol-Myers Squibb), Plavix (Sanofi, Sanofi Winthrop, Sanofi Pharma Bristol-Myers Squibb SNC).

Abciximab is a mouse – human monoclonal antibody fragment which blocks reversibly the platelet GP IIb/IIIa receptor and thus inhibits platelet aggregation regardless of the trigger mechanism. A maximal antiplatelet effect of 80 % receptor blockade is achieved with intravenous bolus injection of 0.25 mg/kg followed by infusion of 0.125 $\mu g kg^{-1} min^{-1}$. After treatment platelet function recovers over several days, but the risk of bleeding is diminished within hours [209]. In large clinical studies abciximab has been investigated as an adjunct to aspirin and heparin in patients undergoing percutaneous coronary revascularization. It was shown that bolus plus infusion of the drug significantly reduced the incidence of ischemic complications (death, myocardial infarction, recurrent ischemia) and improved standard treatment with aspirin and heparin [210]. With respect to the bleeding risk abciximab was so far only tested in high-thrombotic-risk patients. At the moment several new orally active inhibitors of the GP IIb/IIIa receptors are under evaluation [132].

Abciximab [*143653-53-6*], 7E3, c7E3 Fab, immunoglobulin G (human – mousemonoclonal c7E3 clone p7E3V_Hh$C_{\gamma 4}$ Fab fragment anti-humanglycoprotein IIb/IIIa receptor), disulfide with human – mouse monoclonal c7E3 clone p7E3V_KhC_K light chain; for preparation, see [211].

Trade name: ReoPro (Lilly).

5.3.4. Calcium Entry Blockers

Calcium entry blockers (→ Calcium Antagonists) inhibit the transmembrane transport of calcium ions and thus the increase in cytoplasmic calcium ion concentration which is essential for cell activation. Such an action is established in heart muscle cells and smooth muscle cells [212]. In platelets, low concentrations of *verapamil* inhibit calcium uptake and subsequent intracellular epinephrine-induced calcium release and platelet aggregation. Higher concentrations of verapamil are necessary for the inhibition of ADP- and collagen-induced platelet aggregation. The anti-aggregatory effect of verapamil has been demonstrated in both animal experiments and humans [213], [214].

Nifedipine and *diltiazem* also have antiaggregatory activity [215], [216]. There are pronounced differences between these three blockers in their activity patterns against different types of aggregation. These differences are due to the existence of different types of calcium channels or of different ways by which calcium channels are opened [217], [218]. In humans, both verapamil and nifedipine inhibit the forma-

tion of TXA_2 in platelets parallel to the inhibition of aggregation [219]. The knowledge on the antithrombotic action of calcium channel blockers is still very fragmentary. For details on these drugs, see → Calcium Antagonists.

6. Blood Flow Affecting Drugs

Blood flow affecting drugs are compounds that are used for the treatment of occlusive arterial diseases that involve persistent underperfusion of the microcirculation. Such blood flow disorders are generally due to an increased flow resistance. This may be caused either by a decreased vascular cross-section – by passive mechanical obstacles (e.g., atherosclerotic and thrombotic processes) as well as by active vascular constriction (vascular spasm) – or by an increased viscosity of the blood. Compounds used for the remittence of atherosclerotic and thromboembolic processes, as well as for the elimination of vascular spasms are treated elsewhere; therefore, this section describes only compounds that influence the viscosity and hence the flow characteristics of the blood (blood rheology affecting drugs).

6.1. Factors Influencing Blood Viscosity

The viscosity of the blood is determined predominantly by the concentration of red blood cells (hematocrit), and their deformability [220]. Concentration and composition of the plasma proteins have less influence on the viscosity. If one standardizes the relative viscosity of water as 1, that of plasma is about 1.5, and that of blood with a hematocrit of 45 % is about 4.0.

Blood is a non-Newtonian fluid. Therefore, its viscosity is not constant, but is determined by the flow conditions in the vascular network. With decreasing flow rate, the viscosity increases disproportionally; in the case of stasis, viscosity values are so high that the blood loses its ability to flow. This increase in viscosity is the consequence of cross-linking of the red blood cells, which is brought about by fibrinogen, and the formation of rouleau-like aggregates.

At constant flow rate the blood viscosity depends on the vascular diameter. The viscosity falls off to a minimum with decreasing vascular diameter and attains a value that is only about 15 – 20 % higher than that of pure plasma under equivalent flow conditions. In capillaries the red blood cells thus contribute less to the viscosity than in the vessels of the macrocirculation. This optimization of flow dynamics is due to a decrease of the hematocrit in the capillaries to less than half of the systemic hematocrit (Fahraeus-Lindqvist effect) as well as to a deformation of the red blood cells. The high degree of flexibility of the cell membrane and the cell contents and the small cell volume in comparison to the cell surface area are prerequisites for the high degree of deformability of the red blood cells. This effect permits red blood cells to pass through vessels whose diameter is only 40 % that of the cell diameter.

Deformation and flow orientation are made possible through a permanent rotatory movement of the cell membrane around the fluid cell contents (tank track rotation). If the red blood cell loses its flexibility, it will be retained in the microcirculation and subsequently removed by phagocytes. This process normally occurs during the aging of red blood cells in the spleen.

Different factors lead to a loss of red blood cell flexibility, and thus can be of pathogenetic significance. These are acidosis, cell aggregation, change in shape, membrane stiffening, increase of intracellular hemoglobin concentration, and alteration of the surface-to-volume relationship. Hyperviscosity of the blood can moreover be caused by an increase in the hematocrit and an elevation of the protein concentration of the plasma [221]. Hemorheological factors are of pathogenetic significance in such hematological diseases as polycythemia and sickle cell anemia; these factors probably are also very significant in blood flow disorders such as cerebral ischemia, intermittent claudication, myocardial ischemia, and diabetogenic microangiopathy [222].

6.2. Testing of Flow Characteristics of Blood

The flow characteristics of the blood are almost exclusively tested in vitro; only a few experimental investigations under in vivo conditions have been carried out [223]. The clinically important parameters are total blood viscosity and

the extent of aggregation and deformability of the red blood cells. Because of the particular flow dynamics of blood in vivo, investigation of the blood in the rotational viscosimeter is more informative than investigation in the capillary viscosimeter [224], [225]. The following parameters considerably influence the test results: blood sampling technique, type and dosage of anticoagulants, hematocrit, temperature, and age of the blood sample.

One of the ways by which the dynamics of red blood cell aggregation can be assessed is in the rheoscope by determination of the re-aggregation after hydrodynamic dispersion [226].

The flexibility of the red blood cells is preferably determined by filtration of the red blood cell suspension at constant pressure through a pore membrane; the pores of the membrane have a smaller diameter than those of the red blood cells, and their thickness and dimensions must be clearly defined [227].

6.3. Blood Rheology Affecting Drugs

At present the rheological characteristics of the blood can be improved pharmacologically in three ways: by hemodilution, by a decrease of the plasma fibrinogen level, and by optimization of the rheological characteristics of the red blood cells.

6.3.1. Hemodilution

Hemodilution is accomplished through intravenous infusion of crystalloid solutions containing plasma expanders, mostly low molecular mass dextran or human albumin (→ Blood; → Dextran). Depending on the state of cardiac and renal sufficiency, the infusion is carried out in an isovolemic manner (with simultaneous blood withdrawal) or a hypervolemic manner (without blood withdrawal). Persisting hemodilution therapy is only possible by continuous infusion during several days. The blood viscosity is decreased by this measure because the red blood cell count is reduced (decrease in hematocrit of up to 30 %). The blood supply of organs is clearly improved by this method. Such a therapy is effective in acute cerebral ischemia and in peripheral arterial blood supply disorders [228].

6.3.2. Defibrinogenation

The plasma fibrinogen level can be specifically decreased by the parenteral administration of the snake venom enzymes *ancrod* and *batroxobin* [229], [230]. These proteolytic enzymes split off various fibrinopeptides (A, AP, and AY) from fibrinogen, which subsequently polymerize to an unstable form of fibrin that is removed from the circulation by the reticuloendothelial system. This results in a dose-dependent hypofibrinogenemia leading to a decrease in blood viscosity; a decrease in red blood cell aggregation contributes substantially to this effect. As a consequence of the fibrinogen deficiency, platelet aggregation is also diminished [231].

In humans the plasma fibrinogen level begins to fall shortly after the subcutaneous administration of the enzymes and reaches a minimum after some hours. Enteral application has no effect. A decrease of the fibrinogen level down to 70 mg/100 mL is therapeutically desirable; a reduction beyond this value increases the risk of bleeding. To maintain the action, the drug must be administered once or twice a day. After drug withdrawal the plasma fibrinogen level increases slowly and reaches the initial level after several days. With prolonged use the activity of the drug is lost due to the formation of antibodies, because both ancrod and batroxobin are antigenically active. The treatment of humans should therefore not exceed 7 weeks. If resistance occurs during treatment, the action can be maintained by switching from one enzyme to the other because the two enzymes are immunologically different (no cross-reaction). Ancrod and batroxobin are active in different obstructive arterial disorders [229], [232], [233]. Studies in patients with acute ischemic stroke showed that ancrod is safe and effective (more likely than placebo) to achieve functional recovery [234].

Ancrod [*9046-56-4*], *Agkistrodon* serine proteinase, *Agkistrodon rhodostoma* venom proteinase, is a defibrinogenatingenzyme derived from the venom of *Agkistrodon* (new name: *Calloselasma*) *rhodostoma* (Boie), the Malayan pit viper. For its separation from the crude venom, see [235].

The enzyme is a glycopolypeptide with a high carbohydrate content (36 wt %) and a molecular

mass of about 35 400. The polypeptide consists of 18 amino acids [235, a].

When stored at 4 °C either in the lyophilized state (light powdery texture [236]) or as a dilute solution in physiological saline, ancrod is stable for very long periods. At 37 °C its activity is decreased to 50 % within 4 – 6 h [229].

Trade name: Viprinex (Knoll Pharma Inc.).

Batroxobin [*9039-61-6*], *Bothrops* venom proteinase, is a defibrinogenating enzyme derived from the venom of *Bothropsatrox,* a pit viper found in various species in South and Central America [230]. The properties of the agent vary with the subspecies of *Bothrops atrox* from which it is isolated [230], [237, b]. Batroxobin used in therapy is prepared from the subspecies *moojeni* [230]. For the purification of batroxobin from the crude venom of *Bothrops atrox moojeni,* see [237–240].

The enzyme from the venom of *Bothrops atrox moojeni* is a glycopolypeptide with a high carbohydrate content (27 wt %) and a molecular mass of about 29 000. The polypeptide consists of 18 amino acids [237, b].

When stored at 4 °C as a dilute solution in physiological saline, batroxobin is stable for more than 2 years. There is no significant loss in activity if batroxobin is heated in glycerol for 1 h at 100 °C [230].

Trade names: Botropase (Ravizza), Reptilase (Difa-Cooper, Pharma-développement).

6.3.3. Rheological Improvement of Red Blood Cells

Pentoxifylline reduces the viscosity of blood predominantly through an attack on the red blood cells [241]. The flexibility of the red cells is improved, especially in patients with peripheral blood flow disorders. This effect is probably linked to the observed increase in energy-rich phosphate (ATP) in the cell. In addition, the level of fibrinogen in the plasma decreases, which lowers the tendency of the red cells to aggregate [242]. The following additional effects probably contribute to the therapeutic efficacy of the substance: fibrinolytic action [242], inhibition of platelet aggregation, and stimulation of prostacyclin formation [243]. Pentoxifylline has been found to be active in numerous peripheral blood flow diseases [244].

Pentoxifylline [*6493-05-6*], 3,7-dihydro-3,7-dimethyl-1-(5-oxohexyl)-1*H*-purine-2,6-dione, 1-(5-oxohexyl)theobromine, $C_{13}H_{18}N_4O_3$, M_r 278.31, *mp* 105 °C, can be obtained by the methods shown below [245], [246].

(see a: [247])

For other syntheses, see [248–250].

Trade names:Agapurin (medphano), Azupentat (Azupharma), Claudicat (Byk Gulden), durapental (Merck dura), Pento AbZ (AbZ Pharma), Pentoflux (Bouchara), Pentohexal (Hexal), PENTO-PUREN (Isis Puren), pentox von ct (ct-Arzneimittel), Ralofekt (Arzneimittelwerk Dresden, Temmler Pharma), Rentylin (FUISZ PHARMA), Torental (Hoechst), Trental (Hoechst Marion Roussel).

Buflomedil is able to restore the pathologically altered tissue circulation and thus normalize the oxygen supply under experimental conditions [251]. This effect probably depends on (1) a vascular action in the microcirculatory region of the affected tissue and (2) an improved fluidity of the blood caused by increasing the flexibility of the red cells and by inhibiting platelet aggregation [252], [253]. A decrease of oxygen consumption in the tissue caused by this drug has so far only been demonstrated experimentally [254]. In a multicenter study, the value of this substance in obstructive arterial diseases has been established [255].

Buflomedil [*55837-25-7*], 4-(1-pyrrolidinyl)-1-(2,4,6-trimethoxyphenyl)-1-butanone, $C_{17}H_{25}NO_4$, M_r 307.39; hydrochloride [*35543-24-9*], *mp* 192 – 193 °C. Buflomedil is made by treating 1,3,5-trimethoxybenzene with 4-(1-pyrrolidinyl)butyronitrile in the presence of HCl (Houben – Hoesch reaction) [256]:

Buflomedil can also be synthesized by reacting 1,3,5-trimethoxybenzene with 4-chlorobutyryl chloride in the presence of zinc chloride (Friedel – Crafts acylation) and treating the resulting product with pyrrolidine [257]:

Trade names (hydrochloride): Bufedil (Abbott), Bufene (Ist. Chim. Inter.), Buflan (Pierrel), Buflo AbZ (AbZ-Pharma), BUFLO-PUREN (Isis Puren), Buflocit (CT), Buflofar (Farge), Buflohexal (Hexal), Defluina (Rhône-Poulenc Rorer), Emoflux (Metapharma), Flomed (Pulitzer), Fonzylane (Lafon), Irrodan (Biomedica Foscama), Loftyl (Abbott), Medil (Crosara), Perfudan (Piam).

1. Introduction

Catalysis is a phenomenon by which chemical reactions are accelerated by small quantities of foreign substances, called *catalysts*. A suitable *catalyst* can enhance the rate of a thermodynamically feasible reaction but cannot change the position of the thermodynamic equilibrium. Most catalysts are solids or liquids, but they may also be gases.

The catalytic reaction is a cyclic process. According to a simplified model, the reactant or reactants form a complex with the catalyst, thereby opening a pathway for their transformation into the product or products. Afterwards the catalyst is released and the next cycle can proceed.

However, catalysts do not have infinite life. Products of side reactions or changes in the catalyst structure lead to catalyst deactivation. In practice spent catalysts must be reactivated or replaced (see Chapter 9).

1.1. Types of Catalysis

If the catalyst and reactants or their solution form a common physical phase, then the reaction is called *homogeneously catalyzed*. Metal salts of organic acids, organometallic complexes, and carbonyls of Co, Fe, and Rh are typical *homogeneous catalysts*. Examples of *homogeneously catalyzed* reactions are oxidation of toluene to benzoic acid in the presence of Co and Mn benzoates and hydroformylation of olefins to give the corresponding aldehydes. This reaction is catalyzed by carbonyls of Co or Rh.

Heterogeneous catalysis involves systems in the which catalyst and reactants form separate physical phases. Typical *heterogeneous catalysts* are inorganic solids such as metals, oxides, sulfides, and metal salts, but they may also be organic materials such as organic hydroperoxides, ion exchangers, and enzymes.

Examples of *heterogeneously catalyzed* reactions are ammonia synthesis from the elements over promoted iron catalysts in the gas phase and hydrogenation of edible oils on Ni – kieselguhr catalysts in the liquid phase, which are examples of *inorganic*and *organic catalysis*, respectively.

In *biocatalysis*, enzymes or microorganisms catalyze various biochemical reactions. The catalysts can be immobilized on various carriers such as porous glass, SiO_2, and organic polymers. Prominent examples of biochemical reactions are isomerization of glucose to fructose, important in the production of soft drinks, by using enzymes such as glucoamylase immobilized on SiO_2, and the conversion of acrylonitrile to acrylamide by cells of corynebacteria entrapped in a polyacrylamide gel.

The main aim of *environmental catalysis* is environmental protection. Examples are the re-

duction of NO_x in stack gases with NH_3 on $V_2O_5 - TiO_2$ catalysts and the removal of NO_x, CO, and hydrocarbons from automobile exhaust gases by using the so-called *three-way catalyst* consisting of $Rh - Pt - CeO_2 - Al_2O_3$ deposited on ceramic honeycombs.

The term *green catalytic processes* has been used frequently in recent years, implying that chemical processes may be made environmentally benign by taking advantage of the possible high yields and selectivities for the target products, with little or no unwanted side products and also often high energy efficiency.

The basic chemical principles of catalysis consist in the coordination of reactant molecules to central atoms, the ligands of which may be molecular species (homogeneous and biocatalysis) or neighboring atoms at the surface of the solid matrix (heterogeneous catalysis). A1though there are differences in the details of various types of catalysis (e.g., solvation effects in the liquid phase, which do not occur in solid – gas reactions), a closer and undoubtedly fruitful collaboration between the separate communities representing homogeneous, heterogeneous, and biocatalysis should be strongly supported. A statement by David Parker (ICI) during the 21st Irvine Lectures on 24 April 1998 at the University of St. Andrews should be mentioned in this connection, namely, that, "... at the molecular level, there is little to distinguish between homogeneous and heterogeneous catalysis, but there are clear distinctions at the industrial level" [1].

1.2. Catalysis as a Scientific Discipline

Catalysis is a well-established scientific discipline, dealing not only with fundamental principles or mechanisms of catalytic reactions but also with preparation, properties, and applications of various catalysts. A number of academic and industrial institutes or laboratories focus on the study of catalysis and catalytic processes as well as on the improvement of existing and development of new catalysts.

International journals specializing in catalysis include *Journal of Catalysis*, *Journal of Molecular Catalysis*(Series A: Chemical; Series B: Enzymatic), *Applied Catalysis* (Series A: General; Series B: Environmental), *Reaction Kinetics and Catalysis Letters*, *Catalysis Today*, *Catalysis Letters*, *Topics in Catalysis*, *Advances in Organometallic Catalysis*, etc.

Publications related to catalysis can also be found in *Journal of Physical Chemistry*, *Langmuir*, and *Physical Chemistry Chemical Physics*.

Well-known serials devoted to catalysis are *Handbuch der Katalyse* [edited by G.-M. Schwab, Springer, Wien, Vol. 1 (1941) - Vol. 7.2 (1943)], *Catalysis* [edited by P. H. Emmett, Reinhold Publ. Co., Vol. 1 (1954) - Vol. 7 (1960)], *Catalysis – Science and Technology* [edited by J. R. Anderson and M. Boudart, Springer, Vol. 1 (1981) - Vol. 11 (1996)], *Catalysis Reviews* (edited by A. T. Bell and J. J. Carberry, Marcel Dekker), *Advances in Catalysis* (edited by B. C. Gates and H. Knözinger, Academic Press), *Catalysis* (edited by J. J. Spivey, The Royal Society of Chemistry), *Studies in Surface Science and Catalysis* (edited by B. Delmon and J. T. Yates), etc.

Numerous aspects of catalysis were the subject of various books. Some, published since 1980, are mentioned here:

C. N. Satterfield, *Heterogeneous Catalysis in Practice*, McGraw Hill Book Comp., New York, 1980.

D. L. Trimm, *Design of Industrial Catalysts*, Elsevier, Amsterdam, 1980.

J. M. Thomas, R. M. Lambert (eds.), *Characterization of Heterogeneous Catalysts*, Wiley, Chichester, 1980.

R. Pearce, W. R. Patterson (eds.), *Catalysis and Chemical Processes*, John Wiley, New York, 1981.

B. L. Shapiro (ed.), *Heterogeneous Catalysis*, Texas A & M Press, College Station, 1984.

B. E. Leach (ed.), *Applied Industrial Catalysis*, Vol. 1, 2, 3, Academic Press, New York, 1983 – 1984.

M. Boudart, G. Djega-Mariadassou, *Kinetics of Heterogeneous Reactions*, Princeton University Press, Princeton, 1984.

F. Delannay (ed.), *Characterization of Heterogeneous Catalysts*, Marcel Dekker, New York, 1984.

R. Hughes, *Deactivation of Catalysts*, Academic Press, New York, 1984.

M. Graziani, M. Giongo (eds.), *Fundamental Research in Homogeneous Catalysis*, Wiley, New York, 1984.

H. Heinemann, G. A. Somorjai (eds.), *Catalysis and Surface Science*, Marcel Dekker, New York, 1985.

J. R. Jennings (ed.), *Selective Development in Catalysis*, Blackwell Scientific Publishing, London, 1985.

G. Parshall, *Homogeneous Catalysis*, Wiley, New York, 1985.

J. R. Anderson, K. C. Pratt, *Introduction to Characterization and Testing of Catalysts*, Academic Press, New York, 1985.

B. C. Gates, H. Knözinger (eds.), *Impact of Surface Science on Catalysis*, Academic, San Diego, 2000.

A comprehensive survey of the principles and applications: G. Ertl, H. Knözinger, J. Weitkamp (eds.), *Handbook of Heterogeneous Catalysis* with 5 Volumes and 2479 pages was published by VCH, Weinheim, 1997.

The first *International Congress on Catalysis* (ICC) took place in 1956 in Philadelphia and has since been held every four years in Paris (1960), Amsterdam (1964), Moscow (1968), Palm Beach (1972), London (1976), Tokyo (1980), Berlin (1984), Calgary (1988), Budapest (1992), Baltimore (1996), Granada (2000). The 13th Congress will be held in Paris in 2004. Presented papers and posters have been published in the *Proceedings* of the corresponding congresses. *The International Congress on Catalysis Council (ICC)* was renamed at the Council meeting in Baltimore 1996. The international organization is now called *International Association of Catalysis Societies (IACS)*.

In 1965 the *Catalysis Society of North America* was established and holds meetings in the USA every other year.

The European Federation of Catalysis Societies (EFCATS) was established in 1990. The *EUROPACAT* Conferences are organized under the auspices of *EFCATS*. The first conference took place in Montpellier (1993) followed by Maastricht (1995), Cracow (1997), Rimini (1999), and Limerick (2001).

Furthermore, every four years (in the even year between two International Congresses on Catalysis) an *International Symposium* focusing on *Scientific Basis for the Preparation of Heterogeneous Catalysts*is held in Louvain-La Neuve (Belgiüm).

Other international symposia or congresses devoted to catalysis are: *International Zeolite Conferences*, *International Symposium of Catalyst Deactivation*, *Natural Gas Conversion Symposium*, *Gordon Conference on Catalysis*, TOCAT (*Tokyo Conference on Advanced Catalytic Science and Technology*), *International Symposium of Acid-Base Catalysis*, the European conference series, namely the *Roermond, Sabatier- and Schwab-conference*, and the *Taylor Conference*.

1.3. Industrial Importance of Catalysis

Because most industrial chemical processes are catalytic, the importance and economical significance of catalysis is enormous. More than 80 % of the present industrial processes established since 1980 in the chemical, petrochemical, and biochemical industries, as well as in the production of polymers and in environmental protection, use catalysts.

More than 15 international companies have specialized in the production of numerous catalysts applied in several industrial branches. In 1996 the turnover in the catalysts world market was estimated to be about $\$ 8 \times 10^9$ (see Chapter 4).

1.4. History of Catalysis

The phenomenon of catalysis was first recognized by Berzelius [2], [3] in 1835. However, some catalytic reactions such as the production of alcoholic beverages by fermentation or the manufacture of vinegar by ethanol oxidation were practiced long before. Production of soap by fat hydrolysis and of diethyl ether by dehydration of ethanol belong to the catalytic reactions that were performed in the 16th and 17th centuries.

Besides Berzelius, Mitscherlich [3] was also involved at the same time in the study of catalytic reactions accelerated by solids. He introduced the term *contact catalysis*. This term for heterogeneous catalysis lasted for more than 100 years.

In 1895 Ostwald [3], [4] defined catalysis as the acceleration of chemical reactions by the presence of foreign substances which are not consumed. His fundamental work was recognized with the Nobel prize for chemistry in 1909.

Between 1830 and 1900 several practical processes were discovered, such as flameless combustion of CO on a hot platinum wire, and the oxidation of SO_2 to SO_3 and of NH_3 to NO, both over Pt catalysts.

In 1912 Sabatier [3], [5] received the Nobel prize for his work devoted mainly to the hydrogenation of ethylene and CO over Ni and Co catalysts.

The first major breakthrough in industrial catalysis was the synthesis of ammonia from the elements, discovered by Haber [3], [6], [7] in 1908, using osmium as catalyst. Laboratory recycle reactors for the testing of various ammonia catalysts which could be operated at high pressure and temperature were designed by Bosch [3]. The ammonia synthesis was commercialized at BASF (1913) as the *Haber – Bosch* [8] process. Mittasch [9] at BASF developed and produced iron catalysts for ammonia production.

In 1938 Bergius [3], [10] converted coal to liquid fuel by high-pressure hydrogenation in the presence of an Fe catalyst.

Other highlights of industrial catalysis were the synthesis of methanol from CO and H_2 over $ZnO - Cr_2O_3$ and the cracking of heavier petroleum fractions to gasoline using acid-activated clays, as demonstrated by Houdry [3], [6] in 1928.

The addition of isobutane to $C_3 - C_4$ olefins in the presence of $AlCl_3$, leading to branched $C_7 - C_8$ hydrocarbons, components of high-quality aviation gasoline, was first reported by

IPATIEFF et al. [3], [7] in 1932. This invention led to a commercial process of UOP (USA).

Of eminent importance for Germany, which possesses no natural petroleum resources, was the discovery by FISCHER and TROPSCH [11] of the synthesis of hydrocarbons and oxygenated compounds from CO and H_2 over an alkalized iron catalyst. The first plants for the production of hydrocarbons suitable as motor fuel started up in Germany 1938. After World War II, Fischer-Tropsch synthesis saw its resurrection in South Africa. Since 1955 Sasol Co. has operated two plants with a capacity close to 3×10^6 t/a.

One of the highlights of German industrial catalysis before World War II was the synthesis of aliphatic aldehydes by ROELEN [12] by the addition of CO and H_2 to olefins in the presence of Co carbonyls. This homogeneously catalyzed reaction was commercialized in 1942 by Ruhr-Chemie and is known as Oxo Synthesis.

During and after World War II (till 1970) numerous catalytic reactions were realized on an industrial scale (see also Chapter 7). Some important processes are compiled in Table 1.

Table 2 summarizes examples of catalytic processes representing the current status of the chemical, petrochemical and biochemical industry as well as the environmental protection (see also Chapter 7).

2. Theoretical Aspects

The classical definition of a catalyst states that "a catalyst is a substance that changes the rate but not the thermodynamics of a chemical reaction" and was originally formulated by OSTWALD [4]. Hence, catalysis is a dynamic phenomenon.

As emphasized by BOUDART [16], the conditions under which catalytic processes occur on solid materials vary drastically. The reaction temperature can be as low as 78 K and as high as 1500 K, and pressures can vary between 10^{-9} and 100 MPa. The reactants can be in the gas phase or in polar or nonpolar solvents. The reactions can occur thermally or with the assistance of photons, radiation, or electron transfer at electrodes. Pure metals and multicomponent and multiphase inorganic compounds can act as catalysts. Site-time yields (number of product molecules formed per site and unit time) as low as $10^{-5}\ s^{-1}$ (corresponding to one turnover per day) and as high as $10^9\ s^{-1}$ (gas kinetic collision rate at 1 MPa) are observed.

It is plausible that it is extremely difficult, if not impossible, to describe the catalytic phenomenon by a general theory which covers the entire range of reaction conditions and observed site-time yields (reaction rates). However, there are several general *principles* which are considered to be laws or rules of thumb that are useful in many situations. According to BOUDART [16], the value of a principle is directly related to ist generality. In contrast, *concepts* are more specialized and permit an interpretation of phenomena observed for special classes of catalysts or reactions under given reaction conditions.

In this chapter, important principles and concepts of heterogeneous catalysis are discussed, followed by a section on kinetics of heterogeneously catalyzed reactions. The chapter is concluded by a section on the determination of reaction mechanisms in heterogeneous catalysis.

2.1. Principles and Concepts

2.1.1. Sabatier's Principle

The Sabatier principle proposes the existance of an unstable intermediate compound formed between the catalyst surface and at least one of the reactants [5]. This intermediate must be stable enough to be formed in sufficient quantities and labile enough to decompose to yield the final product or products. The Sabatier principle is related to linear free energy relationships such as a Brønsted relation [16]. These relations deal with the heat of reaction q (thermodynamic quantity) and the activation barrier E (kinetic quantity) of an elementary step in the exothermic direction ($q > 0$). With an empirical parameter a ($0 < a < 1$) and neglecting entropy effects, a Brønsted relation can be written as

$$\Delta E = a\,\Delta q,$$

where ΔE is the decrease in activation energy corresponding to an increase Δq in the heat of reaction. Hence, an elementary step will have a high rate constant in the exothermic direction when its heat of reaction q increases. Since the activation barrier in the endothermic direction is equal to the sum of the activation energy E

Table 1. Important catalytic processes commercialized during and after World War II (until 1970) [3], [6]

Year of commercialization	Process	Catalyst	Products
1939 – 1945	dehydrogenation	$Pt - Al_2O_3$	toluene from methylcyclohexane
	dehydrogenation	$Cr_2O_3 - Al_2O_3$	butadiene from *n*-butane
	alkane isomerization	$AlCl_3$	*i*-$C_7 - C_8$ from *n*-alkanes
1946 – 1960	oxidation of aromatics	V_2O_5	phthalic anhydride from naphtalene and *o*-xylene
	hydrocracking	Ni – alumosilicate	fuels from high-boiling petroleum fractions
	polymerization (Ziegler – Natta)	$TiCl_4 - Al(C_2H_5)_3$	polyethylene from ethylene
	dehydrogenation	$Fe_2O_3 - Cr_2O_3 - KOH$	styrene from ethylbenzene
	oxidation (Wacker process)	$PdCl_2 - CuCl_2$	acetaldehyde from ethylene
1961 – 1970	steam reforming	$Ni - \alpha\text{-}Al_2O_3$	Co, (CO_2), and H_2 from methane
	ammoxidation	Bi phosphomolybdate	acrylonitrile from propene
	fluid catalytic cracking	H zeolites + aluminosilicates	fuels from high boiling fractions
	reforming	bimetallic catalysts (Pt, Sn, Re, Ir)	gasoline
	low-pressure methanol synthesis	$Cu - ZnO - Al_2O_3$	methanol from CO, H_2, CO_2
	isomerization	enzymes immobilized on SiO_2	fructose from glucose (production of soft drinks)
	distillate dewaxing	ZSM-5, mordenites	removal of *n*-alkanes from gasoline
	hydrorefining	Ni – , $CO - MoS_x$	hydrodesulfurization, hydrodenitrification

Table 2. Important catalytic processes commercialized after 1970 [6], [7], [13–15]

Year of commercialization	Process	Catalyst	Product
1971 – 1980	automobile emission control	$Pt - Rh - CeO_2 - Al_2O_3$ (three-way catalyst)	removal of NO_x, CO, CH_x
	carbonylation (Monsanto process)	organic Rh complex	acetic acid from methanol
	MTG (Mobil process)	zeolite (ZSM-5)	gasoline from methanol
1981 – 1985	alkylation (Mobil – Badger)	modified zeolite (ZSM-5)	ethylbenzene from ethylene
	selective catalytic reduction (SCR; stationary sources)	V Ti (Mo, W)oxides (monoliths)	reduction of NO_x with NH_3 to N_2
	eserification (MTBE synthesis)	ion-exchange resin	methyl-*tert*-butyl ether from isobutene + methanol
	oxidation (Sumitomo Chem., 2-step process)	1. Mo, Bi oxides 2. Mo, V, PO (heteropolyacids)	acrylic acid from propene
	oxidation (Monsanto)	vanadylphosphate	maleic anhydride from *n*-butane
	fluid-bed polymerization (Unipol)	Ziegler – Natta type	polyethylene and polypropylene
	hydrocarbon synthesis (Shell)	1. $Co - (Zr,Ti) - SiO_2$ 2. $Pt - SiO_2$	middle destillate from $CO + H_2$
	environmental control (combustion process)	$Pt - Al_2O_3$ (monoliths)	deodoration
1986 –	oxidation with H_2O_2 (Enichem)	Ti silicalite	hydroquinone and catechol from phenol
	hydration	enzymes	acrylamide from acrylonitrile
	ammoxidation (Montedipe)	Ti silicalite	cylohexanone oxime from cyclohexanone, NH_3, and H_2O_2
	dehydrogenation of C_3, C_4 alkanes (Star and Oleflex processes)	Pt(Sn) – zinc aluminate, $Pt - Al_2O_3$	C_3, C_4 olefins

and the heat of reaction, the rate constant will decrease with increasing q.

The Brønsted relationship represents a bridge between thermodynamics and kinetics and, together with the Sabatier principle, permits an interpretation of the so-called *volcano plots* first reported by Balandin [17]. These volcano curves result when a quantity correlated with the rate of reaction under consideration is plotted against a measure of the stability of the intermediate compound. The latter quantity can be the heat of adsorption of one of the reactants or the heat of formation of a bulk compound relative to the surface compound, or even the heat of formation of any bulk compound that can be correlated with the heat of adsorption, or sim-

ply the position of the catalytic material (metal) along a horizontal series in the Periodic Table [16].

As an example, Figure 1 shows the volcano plot for the decomposition of formic acid on transition metals [18]. The intermediate in this reaction was shown to be a surface formate. Therefore, the heats of formation ΔH_f of the bulk metal formates were chosen as the measure of the stability of the intermediate. At low values of ΔH_f, the reaction rate is low and corresponds to the rate of adsorption, which increases with increasing heat of formation of the bulk formates (representing the stability of the surface compound). At high values of ΔH_f the reaction rate is also low and corresponds to the desorption rate, which increases with decreasing ΔH_f. As a consequence, a maximum in the rate of reaction (decomposition of formic acid) is observed at intermediate ΔH_f values which is neither a pure rate of adsorption nor a pure rate of desorption but which depends on both.

Figure 1. Volcano plot for the decomposition of formic acid. The temperature T at which the rate of decomposition v has a fixed value is plotted against the heat of formation ΔH_f of the metal formate (adopted from [28]).

2.1.2. The Principle of Active Sites

The Sabatier principle of an unstable surface intermediate requires chemical bonding of reactants to the catalyst surface, most likely between atoms or functional groups of reactant and surface atoms. This leads to the *principle of active sites*. When Langmuir formulated his model of chemisorption on metal surfaces [19], he assumed an array of sites which were energetically identical and noninteracting, and which would adsorb just one molecule from the gas phase in a localized mode. The Langmuir adsorption isotherm results from this model. The sites involved can be considered to be active sites.

Langmuir was already aware that the assumption of identical and noninteracting sites was an approximation which would not hold for real surfaces, when he wrote [20]: "Most finely divided catalysts must have structures of great complexity. In order to simplify our theoretical consideration of reactions at surfaces, let us confine our attention to reactions on plane surfaces. If the principles in this case are well understood, it should then be possible to extend the theory to the case of porous bodies. In general, we should look upon the surface as consisting of a checkerboard." Langmuir thus formulated the surface science approach to heterogeneous catalysis for the first time.

The heterogeneity of active sites on solid catalyst surfaces and its consequences were emphasized by Taylor [21], who recognized that "There will be all extremes between the case in which all atoms in the surface are active and that in which relatively few are so active." In other words, exposed faces of a solid catalyst will contain terraces, ledges, kinks, and vacancies with sites having different coordination numbers. Nanoscopic particles have edges and corners which expose atoms with different coordination numbers [22]. The variation of coordination numbers of surface atoms will lead to different reactivities and activities of the corresponding sites. In this context, Schwab's adlineation theory may be mentioned [23], which speculated that one-dimensional defects consisting of atomic steps are of essential importance. This view was later confirmed by surface science studies on stepped single-crystal metal surfaces [24].

In addition to variable coordination numbers of surface atoms in one-component solids, the surface composition may be different from that of the bulk and different for each crystallographic plane in multicomponent materials (*surface segregation* [25]). This would lead to a heterogeneity of the local environment of a surface atom and thus create nonequivalent sites.

Based on accurate kinetic measurements and on the Taylor principle of the existence of inequivalent active sites, BOUDART et al. [26] coined the terms *structure-sensitive* and *structure-insensitive reactions*. A truly structure-insensitive reaction is one in which all sites seem to exhibit equal activity on several planes of a single crystal. Surprisingly, many heterogeneously catalyzed reactions turned out to be structure-insensitive. Long before experimental evidence for this phenomenon was available and before a reliable interpretation was known, TAYLOR predicted it by writing [21]: "The amount of surface which is catalytically active is determined by the reaction catalyzed." In other words, the surface of a catalyst adapts itself to the reaction conditions for a particular reaction. The driving force for this reorganization of a catalyst surface is the minimization of the surface free energy, which may be achieved by *surface-reconstruction* [27], [28]. As a consequence, a meaningful characterization of active sites requires experiments under working (in situ) conditions of the catalytic system.

The principle of active sites is not limited to metals. Active sites include metal cations, anions, Lewis and Brønsted acids, acid – base pairs (acid and base acting simultaneously in chemisorption), organometallic compounds, and immobilized enzymes. Active sites may include more than one species (or atom) to form multiplets [17] or ensembles [29]. A mandatory requirement for these sites to be active is that they are accessible for chemisorption from the fluid phase. Hence, they must provide free coordination sites. Therefore, BURWELL et al. [30], [31] coined the term *coordinatively unsaturated sites* in analogy with homogeneous organometallic catalysts. Thus, active sites are to be considered as atoms or groups of atoms which are embedded in the surface of a matrix in which the neighboring atoms (or groups) act as ligands. *Ensemble*and *ligand effects* are discussed in detail by SACHTLER [32] and quantum chemical treatments of geometric ensemble and electronic ligand effects on metal alloy surfaces are discussed by HAMMER and NØRSKOV [33].

2.1.3. Surface Coordination Chemistry

The surface complexes formed by atoms or molecules are now known to usually resemble a local structure similar to molecular coordination complexes. The bonding in these surface complexes can well be described in a localized picture [34], [35]. Thus, important phenomena occuring at the surface of solid catalysts may be described in the framework of *surface coordination chemistry* or *surface organometallic chemistry* [36], [37].

This is at variance with the so-called *band theory* of catalysis, which attempted to correlate catalytic performace with bulk electronic properties [38–40]. The shortcomings of this theory in oxide catalysis are discussed by STONE [41].

2.1.4. Modifiers and Promoters

The performance of real industrial catalysts is often adjusted by *modifiers* (additives) [42], [43]. A modifier is called a *promoter* when it increases the catalyst activity in terms of reaction rate per site. Modifiers may also affect a catalyst's performance in an undesired manner. In this case the modifier acts as a catalyst *poison*. However, this simple distinction between promoters and poisons is less straightforward for reactions yielding more than one product in parallel or consecutive steps, of which only one is the desired product. In this case not only high activity but high selectivity is desired. The selectivity can be improved by adding substances that poison undesirable reactions. In exothermic reactions excessively high reaction rates may lead to a significant temperature increase (sometimes only locally: hot spots) which can yield undesirable products (e.g., CO and CO_2 in selective catalytic oxidation). A deterioration of the catalyst due to limited catalyst stability may also occur. Consequently, a modifier is required which decreases the reaction rate so that a steady-state temperature and reaction rate can be maintained. Although the modifier acts as a poison in these cases, it is in fact a promoter as far as selectivity and catalyst stability are concerned.

Modifiers can change the binding energy of an active site or its structure, or disrupt an ensemble of atoms, e.g., by alloying an active with an inactive metal. A molecular approach toward an understanding of promotion in heterogeneous catalysis was presented by HUTCHINGS [44].

As an example, the iron-based ammonia synthesis catalyst is promoted by Al_2O_3 and K_2O [45]. Alumina acts as a *textural* promoter, as it prevents the rapid sintering of pure iron metal. It may also stabilize more active sites on the iron surface (*structural promoter*). Potassium oxide appears to affect the adsorption kinetics and dissociation of dinitrogen and the binding energy of nitrogen on adjacent iron sites (*electronic promoter*).

The addition of Co to MoS_2-based catalysts supported on transitional aluminas has a positive effect on the rate of hydrodesulfuration of sulfur-containing compounds at Co/(Co + Mo) ratios below ca. 0.3 [46] (see Section 3.2.4). The active phase is proposed to be the so-called Co-MoS phase which consists of MoS_2 platelets, the edges of which are decorated by Co atoms. The latter may act as structural and electronic promoters simultaneously.

Another example concerns bifunctional catalysts for catalytic reforming [47], which consist of Pt supported on strongly acidic aluminas, the acid strength of which is enhanced by modification with chloride. Since these materials lose chlorine during the catalytic process, the feed contains CCl_4 as a precursor of the surface chloride promoter.

2.1.5. Active Phase – Support Interactions

Several concepts have proved valuable in interpreting phenomena which are pertinent to certain classes of catalysts. In supported catalysts, the active phase (metal, oxide, sulfide) undergoes active phase-support interactions [48–50]. These are largely determined by the surface free energies of the support and active phase materials and by the interfacial free energy between the two components [48–50]. Active transition metal oxides (e.g., V_2O_5, MoO_3, WO_3) have relatively low surface free energies as compared to typical oxidic support materials such as γ-Al_2O_3, TiO_2 (anatase), and SiO_2. Although the interfacial free energies between active phase and support are not known, the interaction between the two components appears to be favorable, with the exception of SiO_2-supported transition metal oxides. As a consequence spreading and wetting phenomena occur if the thermal treatment of the oxide mixtures is carried out at temperatures sufficiently high to induce mobility of the active oxide. As a rule of thumb, mobility of a solid typically occurs above the Tammann temperature, which is equal to half the melting point of the bulk solid. As a result, the active transition metal oxide tends to wet the support surface and forms a monolayer (monolayer-type catalysts).

Transition and noble metals typically have high surface free energies [49], and therefore, small particles or crystallites tend to agglomerate to reduce their surface area. Stabilization of nanosize metal particles therefore requires deposition on the surface of supports providing favorable *metal-support interactions* (MSI). The smaller the particle the more its physical properties and morphology can be affected by these interactions. Therefore, the nature of the support material for a given metal also critically influences the catalytic properties of the metal particle.

Supported metals are in a nonequilibrium state and therefore still tend to agglomerate at sufficiently high temperatures in reducing atmospheres. Hence, deactivation occurs because of the reduced metal surface area. Regeneration can typically be achieved by thermal treatment in an atmosphere in which the active metal is oxidized. The surface free energies of transition and noble metal oxides are significantly lower than those of the parent metals, so that their spreading on the support surface becomes more favorable. Subsequent reduction under sufficiently mild conditions can restore the high degree of metal dispersion [dispersion D is defined as the ratio of the number of metal atoms exposed at the particle surface (N_S) to the total number of metal atoms N_T in the particle ($D = N_S/N_T$)].

So-called *strong metal-support interactions* (SMSI) may occur, e.g., for Pt – TiO_2 and Rh – TiO_2 [48], [50], [51]. As shown experimentally, the adsorption capacity for H_2 and CO is drastically decreased when the precursor for the catalytically active metal on the support is reduced in H_2 at temperatures above ca. 770 K [48], [51]. Simultaneously, the oxide support

is slightly reduced. Although several explanations have been proposed for the SMSI effect, the most probable explanation is encapsulation of the metal particle by support oxide material. Encapsulation may occur when the support material becomes mobile. Although the electronic properties of the metal particle may be affected by the support oxide in the SMSI state, the decrease of the adsorption capacity appears to be largely due to a geometric effect, namely, the resulting inaccessibility of the metal surface.

The various possible morphologies and dispersions of supported metals are schematically shown in Figure 2. The metal precursor typically is well dispersed after impregnation of the support. Low-temperature calcination may lead to well-dispersed oxide overlayers, while direct low-temperature reduction leads to highly dispersed metal particles. This state can also be reached by low-temperature reduction of the dispersed oxide precursor, this step being reversible by low-temperature reoxidation. For the preparation of highly dispersed Ni catalysts, it is important to remove the water that is formed by hydrogen reduction of NiO. H_2 diluted with N_2 is used for this purpose. Surface compound formation may also occur by a solid-state reaction between the active metal precursor and the support at high calcination temperatures. Reduction at high temperatures may lead to particle agglomeration when cohesive forces are dominant, and to so-called pill-box morphologies when adhesive forces are dominant. In both cases, the metal must be mobile. In contrast, when the support is mobile, sintering of the support can occur, and the small metal particles are stabilized on the reduced surface area (cohesive forces). Alternatively, if adhesive forces are dominant encapsulation (SMSI effect) may occur.

2.1.6. Spillover Phenomena

In multiphase solid catalysts *spillover* may occur of an active species (spillover species) adsorbed or formed on one phase (donor phase) onto a second phase (acceptor) which does not form the active species under the same conditions [53–55]. A well-known example is hydrogen spillover from Pt, on which dihydrogen chemisorbs dissociatively, onto WO_3 with formation of a tungsten bronze [56]. According to SOMORJAI [57] the spillover phenomenon must be regarded as one of the "modern concepts in surface science and heterogeneous catalysis". Nevertheless, the exact physical nature of spillover processes has only rarely been verified experimentally. The term is typically used to explain nonlinear effects (synergistic effects) of the combination of chemically different components of a catalytic material on its performance.

Besides hydrogen spillover, oxygen spillover has been postulated to play an important role in oxidation reactions catalyzed by mixed oxides. For example, the addition of antimony oxide to selective oxidation catalysts enhances the catalytic activity at high levels of selectivity by a factor of up to five relative to the Sb-free system, although antimony oxide itself is completely inactive.

Observations of this kind motivated DELMON et al. [58], [59] to formulate the *remote-control concept* to explain the fact that all industrial catalysts used for the partial oxidation of hydrocarbons or in hydrotreatment are multiphasic and that particular phase compositions develop synergy effects. The remote-control concept is, however, not undisputed.

2.1.7. Phase-Cooperation and Site-Isolation Concepts

GRASSELLI [60] proposed the *phase-cooperation concept* for partial oxidation and ammoxidation reactions. It is suggested that two phases (e.g., α-$Bi_2Mo_3O_{12}$ and γ-Bi_2MoO_6) cooperate in the sense that one phase performs the actual catalytic function (α-phase) and the other (γ-phase) the reoxidation function. The concept could be verified for many other multiphase, multicomponent mixed metal oxide catalysts, such as multicomponent molybdates and multicomponent antimonates [60], [61].

Another concept most relevant for selective oxidation and ammoxidation is the *site-isolation concept* first formulated by CALLAHAN and GRASSELLI [62]. Site isolation refers to the separation of active sites from each other on the surface of a heterogeneous catalyst and is considered to be the prerequisite for obtaining the desired selective partial oxidation products. The concept states that reactive surface lattice oxygen atoms must be structurally isolated

Figure 2. Schematic representation of metal-support interactions (adopted from [47])

from each other in defined groupings on a catalyst surface to achieve selectivity. The number of oxygen atoms in a given isolated grouping determines the reaction channel through the stoichiometry requirements imposed on the reaction by the availability of oxygen at the reaction site. It was postulated that two and up to five adjacent surface oxygen atoms would be required for the selective oxidation of propene to the desired product acrolein. Lattice groupings with more than five oxygen atoms would only produce total oxidation products (CO and CO_2), while completely isolated single oxygen atoms would be either inactive or could produce allyl radicals. The latter would couple in the vapor phase to give hexadiene and ultimately benzene. These scenarios are schematically shown in Figure 3.

2.1.8. Shape-Selectivity Concept

Zeolites and related materials have crystalline structure and contain regular micropores, the diameters of which are determined by the structure of the materials. The pore sizes are well defined and have dimensions similar to those of small organic molecules. This permits *shape-selective catalysis* to occur. The geometric constraints may act on the sorption of reactants, on the transition state of the catalyzed reaction, or on the desorption of products. Correspondingly, shape-selective effects have been classified as providing reactant shape selectivity, restricted transition state shape selectivity, and product shape selectivity [64], [65]. These scenarios are schematically illustrated in Figure 4 for the cracking of *n*-heptane and 1-methylhexane (reactant shape selectivity), for the transalkylation of *m*-xylene (transition state shape selectivity), and for the alkylation of toluene by methanol (product shape selectivity). In the first example, the kinetic diameter of *n*-heptane is smaller than that of 1-methylhexane. The latter is not able to enter micropores, so that shape-selective cracking of *n*-heptane takes place when both hydrocarbons are present in the feed. An example for shape-selective control of the transition state is the transalkylation of *m*-xylene. The reaction is bimolecular and the formation of 1,2,4-trimethylbenzene has a less bulky transition state than the formation of 1,3,5-trimethylbenzene. The latter product can thus not be formed if the pore size and geometry is carefully adapted to the transition state requirements. Finally, p-xylene can be selectively formed by methylation of toluene with methanol and zeolites whose pore openings only allow *p*-xylene to be released. The *o* and *m* isomers either accumulate in zeolite cages or are isomerized to *p*-xylene.

2.1.9. Principles of the Catalytic Cycle

The most fundamental principle in catalysis is that of the *catalytic cycle*, which may be based on a redefinition of a catalyst by Boudart [66]: "A catalyst is a substance that transforms reactants into products, through an *uninterrupted* and *repeated* cycle of elementary steps in which the catalyst is changed through a sequence of *reactive intermediates*, until the last step in the cycle regenerates the catalyst in its original form".

Figure 3. Site-isolation principle. Schematic of lattice oxygen arrangements on hypothetical surfaces. Anticipated reaction paths of propene upon contact with these surfaces (NR = no reaction; adopted from [60])

The catalytic substance or active sites may not be present originally, but may be formed by activation during the start-up phase of the catalytic reaction. The cycle must be uninterrupted and repeated since otherwise the reaction is stoichiometric rather than catalytic. The *number of turnovers*, a measure of catalyst life, must be greater than unity, since the catalyst would otherwise be a reagent. The total amount of catalyst (active sites) is typically small relative to the amounts of reactants and products involved (catalytic amounts). As a consequence, the reactive intermediates can be treated by the kinetic quasi-steady-state approximation of BODENSTEIN.

The *activity* of the catalyst is defined by the number of cycles per unit time or turnovers or turnover frequency (TOF; unit: s^{-1}). The *life* of the catalyst is defined by the number of cycles before it dies.

2.2. Kinetics of Heterogeneous Catalytic Reactions [66–75]

The catalytic cycle is the principle of catalytic action. The mechanism of a catalyzed reaction can be described by the sequence of elementary reaction steps of the cycle, including adsorption, surface diffusion, chemical transformations of

Figure 4. Classification of shape-selective effects

adsorbed species, and desorption, and it is the basis for deriving the kinetics of the reaction. It is assumed that for each individual elementary step the transition-state theory is valid. An early treatize of the kinetics of heterogeneously catalized reactions was published by Schwab [79].

Figure 5. Schematic classification of the various aspects of the dynamics of surface reactions (adopted from [28])

The various aspects of the dynamics of surface reactions and catalysis have been classified by Ertl [28] into five categories in terms of time and length scales, as shown schematically in Figure 5. In the *macroscopic regime*, the rate of a catalytic reaction is modeled by fitting empirical equations, such as power laws, to experimental data, so as to describe its concentration and pressure dependence and to determine rate constants that depend exponentially on temperature. This approach was very useful in chemical engineering for reactor and process design. Assumptions about reaction schemes (kinetic models) provide correlations between the surface coverages of intermediates and the external variables, an approach that led to the Temkin equation [76] modeling the kinetics of ammonia synthesis.

Improved kinetic models could be developed when atomic processes on surfaces and the identification and charaterization of surface species became available. The progress of a catalytic reaction is then described by a *microkinetics* approach by modeling the macroscopic kinetics through correlating atomic processes with macroscopic parameters within the framework of a suitable continuum model. Continuum variables for the partial surface coverages are, to a first approximation, correlated to external parameters (partial pressures and temperature) by the Langmuir lattice model of a surface consisting of identical noninteracting adsorption sites.

The formulation of rate laws for the full sequence of elementary reactions will usually lead to a set of nonlinear coupled (ordinary) differential equations for the concentrations (coverages) of the various surface species involved. The temporal behavior of the reaction system under constant continuous-flow conditions may be nonstationary. In certain parameter ranges it may be oscillatory or even chaotic. Also, there may be local variations in surface coverages which lead to coupling of the reaction with transport processes (e.g., particle diffusion, heat transfer). The formation of spatiotemporal concentration profiles

on a *mesoscopic scale* is the consequence of these nonlinear dynamic phenomena.

Since the Langmuir lattice model is not valid in reality, the continuum model can describe the reaction kinetics only to a first approximation. Interactions between adsorbed species occur, and adsorbed particles occupy nonidentical sites, so that complications arise in the description of the reaction kinetics. Apart from the heterogeneity of adsorption sites, surfaces may undergo structural transformations. Surface science investigations provide information on these effects on an *atomic scale*.

As mentioned above, it is assumed that the transition-state theory is valid for description of the rates of individual elementary steps. This theory is based on the assumption that at all stages along the reaction coordinate thermal equilibrium is established. Temperature then is the only essential external macroscopic parameter. This assumption can only be valid if energy exchange between all degrees of motional freedom of the particles interacting with the solid acting as a heat bath is faster than the elementary step which induces nuclear motions. Energy transfer processes at the *quantum level* are the basic requirements for chemical transformations.

Nonlinear dynamics and the phenomena occuring at the atomic and quantum levels were reviewed by Ertl [28].

2.2.1. Concepts of Reaction Kinetics (Microkinetics)

The important concepts of (catalytic) reaction kinetics were reviewed by Boudart [66], [67], [77], [78], and by Cortright and Dumesic [73].

The term *microkinetics* was defined to denote reaction kinetics analyses that attempt to incorporate into the kinetic model the basic surface chemistry involved in the catalytic reaction at a molecular level [72], [73]. An important prerequisite for this approach is that reaction rates are measured in the absence of heat- and mass-transfer limitations. The kinetic model is based on a description of the catalytic process in terms of information and/or assumptions about active sites and the nature of elementary steps that make up the catalytic cycle. The ultimate goal of a kinetic analysis is the determination of preexponential factors and activation energies (cf. Arrhenius equation) for all elementary steps in forward and reverse direction. Usually there is not sufficient information available to extract the values of all kinetic parameters. However, it has been established that in many cases the observed kinetics are controlled by a limited number of kinetic parameters [72], [73]. Questions to be answered in this situation are: (1) how many kinetic parameters are required to calculate the overall rate from a reaction scheme? (2) What species are the *most abundant intermediates*on the catalyst surface under reaction conditions? (3) Does the reaction scheme include a *rate-determining step* for the kinetic parameters of interest under the reaction conditions? Generally, only a few parameters are kinetically significant, although it is difficult to predict which parameters control the overall rate of the catalytic process. Therefore, initial estimates require a larger set of parameters than are ultimately necessary for the kinetic description of the catalytic process of interest. Besides experimental values of kinetic parameters for individual elementary reactions (often resulting from surface science studies on single-crystal surfaces), quantum chemical calculations permit mechanistic investigations and predicitions of kinetic parameters [33–35].

Assume that a kinetic model has been established which consists of n elementary steps, each proceeding at a net rate

$$r_i = r_{\mathrm{f}i} - r_{\mathrm{r}i} \quad (\mathrm{i} = 1, 2, \ldots, n) \tag{1}$$

The subscripts f and r stand for "forward" and "reverse", respectively. As mentioned above, the validity of the Bodenstein steady-state concept can be assumed. The kinetic steady state is then defined by:

$$\sigma_i r = r_i \tag{2}$$

where r is the net rate $r_{\mathrm{f}} - r_{\mathrm{r}}$ of the overall catalytic reaction defined by a stoichiometric equation. σ_{i} is the stoichiometric number of the ith step, i.e., the number of times that this step must occur for the catalytic cycle to turnover once. If the transition-state theory is valid for each individual elementary step, the ratio of the forward rate $r_{\mathrm{f}i}$ to the reverse rate $r_{\mathrm{r}i}$ of step i is given by the De Donder relation [80], [81]:

$$r_{fi}/r_{ri} = \exp(A_i/RT) \tag{3}$$

where A_i is the affinity of step i:

$$A_i = [\partial G_i/\partial \xi_i]_{T,P} \tag{4}$$

where ξ_i is the extent of reaction of step i.

At steady state, the affinity for each step but one may be very small as compared to the affinity A of the overall reaction. Each step but one is then in quasi-equilibrium. The step that is not in quasi-equilibrium (subscript d) is called the *rate-determining step* (rds) as defined by HORIUTI [82]. As a consequence of this definition, the following inequalities are valid:

$$r_{fi} >> r_{fd}, \text{ and } r_{ri} >> r_{rd} \ (i \neq d).$$

If there is an rds, then the affinity $A_i = 0$ for all values of i except for the rds ($i \neq d$), i.e., all (or almost all) of the affinity for the catalytic cycle is dissipated in the rds, hence

$$A = \sigma_d A_d \tag{5}$$

It follows that

$$r_f/r_r = r_{fd}/r_{rd} \tag{6}$$

At steady state $\sigma_d(r_f - r_r) = r_{fd} - r_{rd}$. Hence

$$\sigma_d r_f = r_{fd} \text{ and } \sigma_d r_r = r_{rd}. \tag{7}$$

The stoichiometric equation for the overall reaction can always be written such that σ_d is equal to unity. It is then clear that the rds is appropriately and uniquely named as the step for which the forward and reverse rates are equal to the forward and reverse rates, respectively, of the overall reaction [66].

Clearly the rds (if there is one) is the only *kinetically significant step*. A kinetically significant step is one whose rate constants or equilibrium constant appear in the rate equation for the overall reaction. In some cases there is no rds in the Horiuti sense, but frequently only a few of the elementary steps in a catalytic cycle are kinetically significant. It is sometimes said that a rate-limiting step is the one having the smallest rate constant. However, rate constants can often not be compared because they have different dimensions.

The relative importance of rate constants of elementary steps in a catalytic cycle provides useful guidelines for the development of activity and selectivity. This can be achieved by *parametric sensitivity analysis* [83], which was first proposed by CAMPBELL [84] for analysis of kinetic parameters of catalytic reactions (see also ref. [73]). CAMPBELL [84] defined a *degree of rate control* for any rate constant k_i in a catalytic cycle turning over at a rate r

$$X_i = k_i/r \cdot \partial r/\partial k_i \tag{8}$$

where the equilibrium constant for step i and all other rate constants are held constant. The main advantage of this mathematical operation is its simplicity. It turns out that HORIUTI's rds, as the only kinetically significant step in a catalytic cycle, has a degree of rate control $X_i = 1$, whereas the X values for all other steps are equial to zero. Clearly, all intermediate values of X_i are possible, and probable in most cases.

As a catalytic cycle turns over at the quasi-steady state, the steady-state concentrations (coverages) of the reactive intermediates may be significantly different from the values that they would attain if they were at equilibrium with fluid reactants or products. The steady-state concentrations (coverages) of reactive intermediates may be lower or higher than the equilibrium values. The reason for this phenomenon is *kinetic coupling* between elementary steps at the steady state, where the net rate of each step is equal to the net rate of the overall reaction multiplied by the stoichiometric number of the step. With kinetic coupling, a reactive intermediate can accumulate as a reactant or be depleted as a product [67], [77], [80].

The principle of *microscopic reversibility* is strictly valid only for reactions at equilibrium. Away from equilibrium, it remains valid provided that transition-state theory is still applicable, which appears to be the case in heterogeneous catalysis [16]. Hence, the principle remains valid for any elementary step in a heterogeneous catalytic reaction. However, the principle must be applied with caution to a catalytic cycle, as opposed to a single elementary reaction. If valid, the principle of microscopic reversibility allows the calculation of a rate constant if the second rate constant and the equilibrium constant K_i of an elementary reaction i are known: $k_{fi}/k_{ri} = K_i$.

2.2.2. Application of Microkinetic Analysis

The ammonia synthesis reaction has been investigated extensively, both on real iron synthesis catalysts and on iron single crystals [45], [85]. Numerous data were therefore available, on the basis of which a reaction model could be established and a microkinetic analysis performed. Ammonia synthesis yields could be theoretically predicted from known kinetic parameters and compared with experimentally measured yields for an industrial iron catalyst. Figure 6 shows the correlation between predicted and experimental yields over a wide range of pressures [86]. The straight line convincingly demonstrates the power of the microkinetic approach.

Figure 6. Comparison of calculated and measured ammonia production over a commercial iron-based catalyst for a broad range of temperatures, pressures, N/H ratios, and gas flows (adopted from [86]).

Additional examples for several other reactions are reviewed in [73].

2.2.3. Langmuir – Hinshelwood – Hougen – Watson Kinetics [63], [69], [71], [87]

The Langmuir – Hinshelwood – Hougen – Watson (LHHW) approach is based on the Langmuir model describing the surface of a catalyst as an array of equivalent sites which do not interact either before or after chemisorption. Further, for derivation of rate equations, it is assumed that both reactants and products are equilibrated with surface species that react on the surface in a rate-determining step. Surface coverages are correlated with partial pressures or concentrations in the fluid phase by means of Langmuir adsorption isotherms. It was mentioned above that the Langmuir model is unrealistic. Moreover, it was demonstrated in Section 2.2.1 that the surface coverages of adsorbed species are by no means identical to the equilibrium values predicted by the Langmuir adsorption isotherm for reaction systems in which kinetic coupling occurs, and rate-determining steps do not generally exist.

Despite these weaknesses, the LHHW kinetics approach has proved valuable for modeling heterogeneous catalytic reactions for reactor and process design. The kinetic parameters which are determined by fitting the rate equations to experimental data, however, do not have a straightforward physical meaning. As an alternative, simple power-law kinetics for straightforward reactions (e.g., $A \rightarrow B$) can be used for technical application.

Often it is difficult to discriminate between two or more kinetic models within the accuracy limits of the experimental data. Sophisticated mathematical procedures have therefore been developed for the discrimination of rival models [88].

As an example for a typical LHHW rate equation consider the reaction

$$A + B \rightleftharpoons C.$$

The form of rate equation is as follows [88]:

$$r = \frac{k_{\mathrm{rds}} N_{\mathrm{T}} K_i \left(P_{\mathrm{A}} P_{\mathrm{B}} - P_{\mathrm{C}}/K_{\mathrm{eq}}\right)}{\left(1 + K_{\mathrm{A}} P_{\mathrm{A}} + K_{\mathrm{B}} P_{\mathrm{B}} + K_{\mathrm{C}} P_{\mathrm{C}} + \sum_j K_{\mathrm{j}} P_{\mathrm{j}}\right)^{\mathrm{n}}} = \frac{\text{rate factor} \times \text{driving force}}{\text{inhibition term}} \tag{9}$$

The numerator is a product of the rate constant of the rds k_{rds}, the concentration of active sites N_{T}, adsorption equilibrium constants K_i, and the driving force for the reaction. The latter is a measure of how far the overall reaction is from thermodynamic equilibrium. The overall equilibrium constant K_{eq}, can be calculated from thermodynamics. The denominator is an inhibition term which takes into account the competitive adsorption of reactants and products.

A few examples of LHHW rate equations are summarized in Table 3. A collection of useful LHHW rate equations and kinetic data for almost 100 industrially important catalytic reactions is available in [89].

Table 3. General structure of Langmuir type rate equations [87]

	Reaction	Controlling step	Net rate	Kinetic constant	Driving force	Adsorption term
1.	$A \rightleftharpoons P$	a. adsorption of A	$k_A p_A(1-\Sigma\Theta) - k_A'\Theta_A$	k_A	$p_A - \frac{p_P}{K}$	$1+K_A p_A + K_P p_P$
		b. surface reaction single-site mechanism	$k_S\Theta_P - k_S'\Theta_P$	$k_S K_A$	$p_A - \frac{p_P}{K}$	$1+K_A p_A + K_P p_P$
		c. desorption of P	$k_P'\Theta_P - k_P p_P(1-\Sigma\Theta)$	$k_P' k_S K_A$	$p_A - \frac{p_P}{K}$	$1+K_A p_A + K_P p_P$
2.	$A \rightleftharpoons P+Q$	surface reaction, A (ads) reacts with vacant site	$k_S\Theta_A(1-\Sigma\Theta) - k_S\Theta_P$	$k_S K_A$	$p_A - \frac{p_P p_Q}{K}$	$(1+K_A p_A + K_P p_P + K_Q p_Q)^2$
3.	$A_2 \rightleftharpoons 2P$	a. dissociative adsorption of A_2	$k_A p_{A_2}(1-\Sigma\Theta)^2 - k_A'\Theta_A$	k_A	$p_{A_2} - \frac{p_P^2}{K}$	$(1+K_A p_{A_2} + K_P p_P)^2$
		b. surface reaction following dissociative adsorption of A_2	$k_S\Theta_A - k_S'\Theta_P$	$k_S K_A$	$p_{A_2} - \frac{p_P}{K}$	$1+K_A p_{A_2} + K_P p_P$
4.	$A+B \rightleftharpoons P$	a. adsorption of A	$k_A p_A(1-\Sigma\Theta) - k_A'\Theta_A$	k_A	$p_A - \frac{p_P}{K p_B}$	$1+K_A p_A + K_B p_B + K_P p_P$
		b. surface reaction	$k_S\Theta_A\Theta_B - k_S'\Theta_P(1-\Sigma\Theta)$	$k_S K_A K_B$	$p_A p_B - \frac{p_P}{K}$	$(1+K_A p_A + K_B p_B + K_P p_P)^2$
		c. desorption of p	$k_P'\Theta_P - k_P p_P(1-\Sigma\Theta)$	$k_P' K_S K_A K_B$	$p_A p_B - \frac{p_P}{K}$	$1+K_A p_A + K_B p_B + K_P p_P$
5.	$\frac{1}{2}A+B \rightleftharpoons P$	dissociative adsorption of A_2, only half of which react	$k_A p_{A_2}(1-\Sigma\Theta) - k_A'\Theta_A$	k_A	$p_{A_2} - \frac{p_P}{K p_B}$	$1+K_A p_{A_2} + K_B p_B + K_P p_P$
6.	$A+\frac{1}{2}B \rightleftharpoons P$	adsorption of A, which reacts with half of B produced from the dissociative adsorption of B_2	$k_A p_A(1-\Sigma\Theta) - k_A'\Theta_A$	k_A	$p_A - \frac{p_P}{K p_{B_2}}$	$1+K_A p_A + K_B p_{B_2} + K_P p_P$
7.	$A_2+2B \rightleftharpoons 2P$	a. dissociative adsorption of A_2	$k_A p_{A_2}(1-\Sigma\Theta)^2 - k_A'\Theta_{A^2}$	k_A	$p_{A_2} - \frac{p_P^2}{K p_{B_2}}$	$1+K_A p_A + K_B p_B + K_P p_P$
		b. surface reaction following the dissociative of adsorption A	$k_S\Theta_A\Theta_B - k_S' p(1-\Sigma\Theta)$	$k_S K_A K_B$	$p_{A_2} p_B - \frac{p_P}{K}$	$1+K_A p_{A_2} + K_B p_B + K_P p_P$

2.2.4. Activity and Selectivity

Catalytic activity is expressed in terms of reaction rates, preferably normalized to the surface area of the active phase (e.g., metal surface area for supported metal catalysts). These surface areas can be obtained by suitable chemisorption techniques (see Section 5.1). As an alternative to these *areal rates*, *specific rates* are also used which are normalized to catalyst weight. The best possible measure of catalytic activity, however, is the *turnover rate* or *turnover frequency*, since it is normalized to the number of active sites and represents the rate at which the catalytic cycle turns over. For comparison of rates reported by different research groups, the methodology for the determination of the number of active sites must be carefully reported. The hitherto unresolved problem is that the site densities measured prior to the catalytic reaction are not necessarily identical to those available under reaction conditions.

A readily available measure of catalytic activity is *space–time yield*, expressed in units of amount of product made in the reactor per unit time and unit reactor volume.

A considerable obstacle for the comparison of catalytic activities for a given reaction that were obtained in different laboratories for the same catalyst is the use of different reactors. For a series of catalysts, reasonable comparisons of activities or rates are possible when relative values are used.

Conversion data alone, or conversion versus time plots are not sufficient as a measure of catalytic activity.

Selectivity can be defined as the amount of desired product obtained per amount of consumed reactant. Selectivity values are only useful if the conversion is also reported. A simple measure of selectivity is the *yield* (yield = selectivity × conversion). Selectivities can also be used to indicate the relative rates of two or more competing reactions; competition may occur when several reactants form products in parallel (type I):

when one reactant transforms into several products in parallel (type II):

or in consecutive reactions (type III):

The selectivity is defined as the ratio of the rate of formation of the desired product to the rate of consumption of the starting material [90]. Thus, the selectivities for product X for the first-order reactions I and II is $r_1/(r_1 + r_2)$, whereas it is $(r_1 - r_2)/r_1$ for type III.

In the case of type I or II reactions, selectivity for X or Y is independent of the conversion of the starting material. In type III reactions, the selectivity for X is 100 % initially, decreases gradually with increasing conversion, and drops to zero at 100 % conversion. At an intermediate conversion, there is a maximum yield of X which depends on the ratio of the rate constants k_1 and k_2 of the rates r_1 and r_2. The integrated rate equations are:

$$[\mathrm{A}] = \exp(-k_1 t) \tag{10}$$

$$[\mathrm{X}] = k_1/(k_2 - k_1)\,[\exp(-k_1 t) - \exp(-k_2 t)] \tag{11}$$

where [A] is the concentration of unconverted A, [X] the concentration of A converted to product X, and t time. The maximum yield is reached at

$$t = (k_1 - k_2)^{-1} \ln(k_1/k_2) \tag{12}$$

2.3. Determination of Catalytic Mechanisms [31]

The best description of a catalytic mechanism is the corresponding catalytic cycle. As a first step, a detailed product analysis is required to differentiate between a single clean reaction and systems undergoing parallel and/or consecutive reactions. The microkinetic approach, as outlined in Sections 2.2.1 and 2.2.2, for the predicition of the overall rate of a catalytic reaction taking into account the surface chemistry of the catalyst and the elementary reactions involved, is the most promising procedure to predict a mechanism.

However, the results of microkinetic analyses may not always be unequivocal, and the discrimination between different kinetic models may not be straightforward. Therefore, additional information is necessary to prove or disprove the sequence of elementary steps (catalytic cycle) that represent the mechanism of a catalyzed reaction at the molecular level.

Quantum chemical calculations at various levels of sophistication and computer modeling procedures are available today [33–35], [91], [92] which permit structures of adsorbed intermediates and transition states to be elucidated and reaction energy diagrams to be computed.

Transient kinetics measurements can also provide quantitative values of kinetic parameters and the elucidation of individual reaction steps [93], [94]. Pulse reactors are one type of transient reactors. The TAP reactor (temporal analysis of products) is discussed in Section 8.1.2. In another kind of transient experiment, step changes in concentrations are effected, and the response of product concentration is measured as a function of time. The analysis of this response provides details of the course of reaction and permits kinetic parameters to be determined.

A powerful technique for the kinetic and mechanistic study of heterogeneous catalytic reactions is steady-state isotopic-transient kinetic analysis (SSITKA) [94], [95]. The technique is based on the detection of isotopic labels in the reactor effluent species versus time following a step change in the isotopic labeling of one of the reactants in the reactor feed. Reactant and product concentrations and flow rates remain undisturbed during the step change and – in the absence of isotopic mass effects – steady-state conditions are maintained unter isotopic-transient operation. In contrast to other transient experiments, the steady-state kinetic behavior of the catalyst surface can be studied. Steady-state kinetic and mechanistic information which can be obtained from SSITKA includes concentrations of different types of adsorbed reaction intermediates, coverages, surface lifetimes, site heterogeneity, activity distributions, and identification of possible mechanisms [94].

The use of isotopes can greatly aids the elucidation of catalytic mechanisms [96]. The most frequently used isotopes are ^{2}H, ^{13}C, ^{14}C, and ^{18}O. Deuterium-exchange reactions with organic reactants yield isotopic distribution patterns, i.e., the fractions of the isotopically exchanged molecules, D_1, D_2, ... , where D_i is the fraction of the compound containing *i* deuterium atoms. These isotopic distribution patterns are often specific enough to eliminate a number of conceivable mechanisms. When carried out in conjunction with structure variations, isotopic distribution patterns may be effective in narrowing the range of possible mechanisms even though such studies cannot give "the mechanism" [31]. Deuterium labeling is also used to determine which carbon atoms end up where or whether a reaction is inter- or intramolecular [31]. ^{13}C labeling can be used for the same purpose. Although nonradioactive labels are preferred, radioactive tracers such as ^{14}C have also been used [97]. ^{18}O labeling has been applied to elucidate the relative rates of CO and CO_2 in methanol synthesis [98].

Kinetic isotope effects [99], [100] are due to the different masses of a given element and its corresponding isotope. The resulting difference in zero-point energies may lead to an increase in activation energy of the labeled molecule and therefore a reduction of the rate. Whether a kinetic isotope effect occurs or not when isotopic labeling exists for an atom in a certain position or group (say hydrogen in an X – H bond replaced by X – D) for a catalytic reaction of interest provides information on whether the weakening or rupture of the X – H bond is involved in a kinetically significant elementary step.

Modification of organic molecules with suitable substituent groups may provide valuable information on reaction mechanisms from the stereochemistry of the reaction of interest [31], [102], [103]. Substituents generally also have electronic effects on the reactivity of a parent reactant (substituent effects). Resulting linear free-energy relationships for a series of substituents also assist the determination of kinetically significant reaction steps of a conceivable reaction mechanism [104–107], since the substituents directly affect the relative energy of the transition state and hence the activation barrier of a kinetically significant step.

Modification of molecules by substituents may also cause intra- or intermolecular steric effects [31] and steric interactions between adsorbate and catalyst surface can be studied. The latter studies provide almost the only way to directly probe the steric nature of active catalytic

sites without confusion with adsorption sites that are not catalytic sites [31].

Selective feeding and scavenging has been proposed for the characterization of reaction intermediates [31]. Suppose Q is a suspected intermediate for a particular reaction. This hypothesis can be tested by adding (feeding) a compound to the reaction feed which is supposedly adsorbed to form the suspected intermediate Q, and by testing whether the added compound is indeed converted to the expected product. In scavenging, a compound is added which should react with the intermediate Q to form another compound which is not normally a product.

The nature of catalytic sites can be tested and their density estimated by selective poisoning [108].

Of course, any spectroscopic technique which is surface-sensitive and which has sufficiently high sensitivity and can be applied under catalytic working conditions can provide valuable information on the nature of sufficiently long-lived intermediates. However, spectroscopy often detects spectator species rather than reaction intermediates. Therefore it is mandatory to demonstrate that true intermediates are in fact seen. This can be done by varying critical reaction parameters and monitoring the response of spectroscopic signal intensities as a function of time. Sufficiently high time resolution of the applied spectroscopic technique is therefore required (see Chapter 5).

3. Classification of Solid Catalysts

Solid catalysts are extremely important in large-scale processes [109–113] for the conversion of chemicals, fuels, and pollutants. Many solid materials (elements and compounds) including metals, metal oxides, and metal sulfides, are catalysts. Only a few catalytic materials used in industry are simple in composition, e.g., pure metals (e.g., Ni) or binary oxides (such as γ-Al_2O_3, TiO_2). Typical industrial catalysts, however, consist of several components and phases. This complexity often makes it difficult to assess the catalytic material's structure.

In the following a variety of families of existing catalysts are described, and selected examples are given. These families include (1) unsupported (bulk) catalysts; (2) supported catalysts; (3) confined catalysts (ship-in-a-bottle catalysts); (4) hybrid catalysts; (5) polymerization catalysts, and several others. The selected examples not only include materials which are in use in industry, but also materials which are not yet mature for technological application but which have promising potential.

3.1. Unsupported (Bulk) Catalysts

3.1.1. Metal Oxides

Oxides are compounds of oxygen in which the O atom is the more strongly electronegative component. Oxides of metals are usually solids. Their bulk properties largely depend on the bonding character between metal and oxygen. Metal oxides have widely varying electronic properties and include insulators (e.g., Al_2O_3, SiO_2), semiconductors (e.g., TiO_2, NiO, ZnO), metallic conductors (typically reduced transition metal oxides such as TiO, NbO, and tungsten bronzes), superconductors (e.g., $BaPb_{1-x}Bi_xO_3$), and high-T_c superconductors (e.g., $YBa_2Cu_3O_{7-x}$).

Metal oxides make up a large and important class of catalytically active materials, their surface properties and chemistry being determined by their composition and structure, the bonding character, and the coordination of surface atoms and hydroxyl groups in exposed terminating crystallographic faces. They can develop acid-base and redox properties. Metal oxides can have simple composition, like binary oxides, but many technologically important oxide catalysts are complex multicomponent materials.

3.1.1.1. Simple Binary Oxides

Simple binary oxides of base metals may behave as solid acids or bases or amphoteric materials [114]. These properties are closely related to their dissolution behavior in contact with aqueous solutions. Amphoteric oxides (e.g., Al_2O_3, ZnO) form cations in acidic and anions in basic milieu. Acidic oxides (e.g., SiO_2) dissolve with formation of acids or anions. Transition metal oxides in their highest oxidation state (e.g., V_2O_5, CrO_3) behave analogously. Basic oxides (e.g., MgO, lanthanide oxides) form hydroxides

or dissolve by forming bases or cations. These dissolution properties must be considered when such oxides are used as supports and impregnated from aqueous solutions of the active phase precursor [115], [116]. The dissolution properties also are closely related to the surface properties of the oxides in contact with a gas phase, where the degree of hydration/hydroxylation of the surface is a critical parameter. Silica, alumina and magnesia are commonly used catalysts and catalyst supports representative for a wide range of surface acid – base properties.

Aluminas are amphoteric oxides, which form a variety of different phases depending on the nature of the hydroxide or oxidehydroxide precursor and the conditions of their thermal decomposition. Bayerite, nordstrandite, boehmite, and gibbsite can be used as starting materials. The thermal evolution of the various poorly crystalline transitional phases (namely η-, Θ-, γ-, χ-, and κ-Al_2O_3) and of the final crystalline, thermodynamically stable α-Al_2O_3 phase (corundum) is shown in Figure 7. The structures of these oxides can be described as close-packed layers of oxo anions with Al^{3+} cations distributed between tetrahedral and octahedral vacancy positions. Stacking variations of the oxo anions result in the different crystallographic forms of alumina. The most commonly used transitional phases are η- and γ-Al_2O_3, which are often described as defect spinel structures [117] that incorporate Al^{3+} cations in both tetrahedral and octahedral sites. The Al sublattice is highly disordered, and irregular occupation of the tetrahedral interstices results in a tetragonal distortion of the spinel structure. There is a higher occupancy of tetrahedral cation positions in γ-Al_2O_3, and a higher density of stacking faults in the oxygen sublattice of η-Al_2O_3. Crystallites are preferentially terminated by anion layers, and these layers are occupied by hydroxyl groups for energetic reasons [118].

Acidic and basic sites and acid-base pair sites have been identified on the surfaces of aluminas [119]. Thermal treatment of hydroxylated oxides leads to partial dehydroxylation with formation of coordinatively unsaturated O^{2-} ions (basic sites) and an adjacent anion vacancy which exposes 3- or 5-coordinate Al^{3+} cations (Lewis acid sites). The remaining hydroxyl groups can be terminal or doubly or triply bridging with the participation of Al^{3+} in tetrahedral and/or octahedral positions. The properties of the resulting OH species range from very weakly Brønsted acidic to rather strongly basic and nucleophilic [118], [119]. As a result of this complexity, alumina surfaces develop a rich surface chemistry and specific catalytic properties [120].

Besides their intrinsic catalytic properties and their use as catalysts in their own right (e.g., for elimination reactions, alkene isomerization [120], and the Claus process [121]), aluminas are frequently used as catalyst supports for oxides and metals. The surface area and particle size of aluminas can be controlled by the preparation conditions, and their redox and thermal stability give the supported active phases high stability and ensure a long catalyst lifetime.

Silicas are weakly Brønsted acidic oxides which occur in a variety of structures such as quartz, tridymite and cristobalite (→ Silica) [122], [123]. The most commonly used silica in catalysis is amorphous silica. The building blocks of silica are linked SiO_4 tetrahedra, with each O atom bridging two Si atoms. Bonding within the solid is covalent. At the fully hydrated surface, the bulk structure is terminated by hydroxyl (silanol) groups, SiOH [119], [122], [123]. Two types of these groups are usually distinguished: isolated groups and hydrogen-bonded vicinal groups. Fully hydrated samples, calcined at temperatures below 473 K, may contain geminal groups $Si(OH)_2$ [119], [122], [123]. Heating in vacuum removes the vicinal groups by dehydroxylation, i.e., condensation to form H_2O and Si – O – Si linkages (siloxane bridges). Complete removal of the hydroxyl groups occurs at temperatures well above 973 K in vacuo and is believed to result in significant changes in surface morphology.

The surface hydroxyl groups are only weakly Brønsted acidic and therefore hardly develop any catalytic activity. They are, however, amenable to hydrogen-bonding [124] and they are usually regarded as the most reactive native surface species, which are available for functionalization of silicas. The siloxane bridges are (at least after heating at elevated temperatures) essentially unreactive. For this reason and because of the low acidity of silanol groups, silicas are not used as active catalysts, but they play an important role as oxide supports and for the

Figure 7. The dehydration sequences of the aluminum trihydroxides in air (adopted from [117])

synthesis of functionalized oxide supports (see Section 3.2.5).

Tailored silicas can be synthesized by controlling the preparation conditions [122], [123]. Thus, surface area, particle size and morphology, porosity and mechanical stability can be varied by modification of the synthesis parameters.

In addition to amorphous silicas, the crystalline microporous silica silicalite I can be obtained by hydrothermal synthesis [125]. This material has MFI structure and can be considered as the parent siliceous extreme of zeolite ZSM-5.

Large-pore mesoporous structures, the so-called porosils, have also been reported [125–127]. The dimensions of their linear and parallel pores can be varied from 2 to 10 nm in a regular fashion. These pores can therefore accomodate bulky molecules and functional groups.

The incorporation of foreign elements such as Al^{3+} substituting for Si^{4+} induces Brønsted acidity and creates activity for acid catalysis.

Magnesium oxide is a basic solid. It has the simple rock salt structure, with octahedral coordination of magnesium and oxygen. Ab inito molecular orbital calculations indicated that the electronic structure is highly ionic, with the $Mg^{2+}O^{2-}$ formalism being an accurate representation of both bulk and surface structures [128]. The lattice is commonly envisaged to terminate in (100) planes incorporating five-coordinate (5c) Mg^{2+} and O^{2-} ions [129] (see Figure 8). This model appears to be physically accurate for MgO smoke, which may be regarded as a model crystalline metal oxide support [130]. Although the (100) plane is electrically neutral, hydroxyl groups are present on the surfaces of polycrystalline MgO. These groups and the O^{2-} anions are responsible for the basic properties, coordinatively unsaturated Mg^{2+} ions being only weak Lewis acid sites. The hydroxyl groups are also highly nucleophilic.

These properties dominate the surface chemistry of MgO. Organic Brønsted acids have been shown to chemisorb dissociatively to form surface-bound carbanions and surface hydroxyl groups [131]. Even the heterolytic dissociative adsorption of dihydrogen on polycristalline MgO has been reported. $Mg^{2+}O^{2-}$ pairs with Mg^{2+} and O^{2-} in 4- or 3-coordination seem to play a crucial role.

The presence of low-coordinate Mg^{2+} and O^{2-} ions (see Figure 8) on the MgO surface after activation at high temperatures has been demonstrated [129], [132], [133], and the unique reactivity of 3c centers has been discussed [134].

MgO has also been used as a host matrix for transition metal ions (**solid solutions**) [135]. These materials permit the properties of isolated transition metal ions to be studied.

Transition metal oxides [136–138] can be struturally described as more or less dense packings of oxide anions, the interstices of which are occupied by cations. The bonding, however, is never purely ionic, but rather mixed ionic-covalent, sometimes also developing metallic character (e.g., bronzes). The surface of these oxides is often partially occupied by hydroxyl groups, so they possess some acidic character. However, it is the variability in oxidation states and the possibility of forming mixed-valence and nonstoichiometric compounds that are responsible for their important redox catalytic properties. The most frequently used transition metal oxides are those of the early transition metals (mostly suboxides). Fields of application are particularly selective oxidation and dehydrogenation reactions.

Figure 8. Representation of a surface plane (100) of MgO showing surface imperfections such as steps, kinks, and corners wich provide sites for ions of low coordination (adopted from [129]).

Titania TiO_2 exists in two major crystallographic forms: anatase and rutile. Anatase is the more frequently used modification since it develops a larger surface area, although it is a metastable phase and may undergo slow transformation into the thermodynamically stable rutile phase above ca. 900 K. Vanadium impurities seem to accelerate the rutilization above 820 K. Other impurities such as surface sulfate and phosphate seem to stabilize the anatase phase. The anatase $\rightarrow$ rutile phase transition must be sensitively controlled for supported VO_x/TiO_2, which plays a significant role in selective oxidation and NO_x reduction catalysis.

Titania is a semiconductor with a wide band gap and as such is an important material for photocatalysis [139], [140].

Zirconia has attracted significant interest in the recent past as a catalyst support and as a base material for the preparation of strong solid acids by surface modification with sulfate or tungstate groups [141]. The most important crystallographic phases of ZrO_2 for catalytic applications are tetragonal and monoclinic. The latter is the thermodynamically stable phase. Higher surface areas, however, are developed by the metastable tetragonal phase, which is stabilized at low temperatures by sulfate impurities or intentional addition of sulfate or tungstate.

ZrO_2 is the base material for the solid-state electrolyte sensor for the measurement of oxygen partial pressure in, e.g., car exhaust gases [142]. The solid electrolyte shows high bulk conductivity for O^{2-} ions.

Other transition metal oxides are used as supported catalysts or as constituents of complex multicomponent catalysts.

Only a few examples are reported on the application of the unsupported binary oxides as catalysts. Iron oxide Fe_2O_3 and chromium oxide Cr_2O_3 catalyze the oxidative dehydrogenation of butenes to butadiene. Fe_2O_3-based catalysts are used in the high-temperature water gas shift reaction [143] and in the dehydrogenation of ethylbenzene [144]. Vanadium pentoxide V_2O_5 is active for the selective oxidation of alkenes to saturated aldehydes [145]. Acidic transition metal oxides such as vanadium pentoxide and molybdenum trioxide MoO_3 can be used for the synthesis of formaldehyde by oxidative dehydrogenation of methanol, while the more basic iron oxide Fe_2O_3 leads to total oxidation [146]. Zinc oxide ZnO is used as a catalyst for the oxidation of cyclohexanol to cyclohexanone.

3.1.1.2. Complex Multicomponent Oxides

Complex multicomponent oxides play a major role as catalytic materials.

Aluminium silicates are among the most important ternary oxides. Four-valent Si atoms are isomorphously substituted by trivalent Al atoms in these materials. This substitution cre-

ates a negatively charged framework of interconnected tetrahedra. Exchangeable cations are required for charge compensation when protons are incorporated as charge-compensating cations, OH groups bridging Si and Al atoms are created which act as Brønsted acidic sites.

Amorphous silica – alumina can be prepared by precipitation from solution. This mixed oxide is a constituent of hydrocarbon cracking catalysts.

Zeolites. Hydrothermal synthesis can be used for preparation of a large family of crystalline aluminosilicates, known as *zeolites* (→ Zeolites), which are microporous solids with pore sizes ranging from ca. 3 to 7 Å [125], [147], [148]. Characteristic properties of these structurally well-defined solids are selective sorption of small molecules (molecular sieves), ion exchange, and large surface areas. Zeolites possess a framework structure of corner-linked SiO_4^{4-} and AlO_4^{5-}-tetrahedra with two-coordinate oxygen atoms that bridge two tetrahedral centers (so-called T atoms). Zeolite frameworks are open and contain channels (straight or sinusoidal) or cages of spherical or other shapes. These cages are typically interconnected by channels. The evolution of several zeolite structures from the primary tetrahedra via secondary building blocks is demonstrated in Figure 9 [149]. The diameter of the channels is determined by the number n of T atoms surrounding the opening of the channels as n-membered rings. Small-pore zeolites contain 6- or 8-membered rings (diameter d: $2.8 < d < 4$ Å), medium-pore zeolites contain 10-membered rings ($5 < d < 6$ Å) and the openings of large-pore zeolites are constructed of 12-membered rings ($d > 7$ Å). Examples of small-pore zeolites are sodalite and zeolite A, of medium-pore zeolites ZSM-type zeolites (see Figure 9), while large-pore zeolites include faujasites and zeolites X and Y (see Figure 9).

The H forms of zeolites develop strong Brønsted acidity and play a major role in large-scale industrial processes such as catalytic cracking, the Mobil MTG (methanol-to-gasoline) process and several others.

Besides Si and Al as T atoms P atoms can also be incorporated in zeolite structures. In addition, transition metal atoms such as Ti, V, and Cr can substitute for Si, which leads to oxidation catalysts of which titanium-silicalite-1 (TS1) is the most outstanding catalyst for oxidation, hydroxylation, and ammoxidation with aqueous H_2O_2 [150].

Basic properties can be created in zeolites by ion-exchange with large alkali metal ions such as Cs^+ and additional loading with CsO [151].

Aluminum phosphates (AlPO) [152], [153] are another family of materials whose structures are similar to those of zeolites. They can be regarded as zeolites in which the T atoms are Si and Al. More recently they have been named zeotypes, the T atoms of which are Al and P. In contrast to aluminosilicate zeolites, AlPOs typically have a Al/P atomic ratio of 1/1, so that the framework composition $[AlPO_4]$ is neutral. Therefore, these solids are nonacidic and have hardly any application as catalysts. However, acidity can be introduced by substituting Al^{3+} by divalent atoms, which yields *metal aluminophosphates* (MAPOs), e.g., MnAPO or CoAPO, or by partial substitution of formally pentavalent P by Si^{4+} to give *silicoaluminophosphates* (SAPO). The AlPO family contains members with many different topologies which span a wider range of pore diameters than aluminosilicate zeolites.

Mesoporous solid acids with well-defined pore structures can be obtained by replacing a certain amount of Si atoms in MCM-type oxides by Al atoms.

Clays (→ Clays) are aluminosilicate minerals (montmorillonite, phyllosilicates (smectites), bentonites, and others). Montmorillonite is an aluminohydroxysilicate and is the main constituent of most clay minerals. It is a 2 : 1 clay, i.e., one octahedral AlO_6 layer is sandwiched between two tetrahedral SiO_4 layers. Montmorillonites are reversibly swellable and possess ion-exchange capacity. They can be used as catalyst supports. The structural layers can be linked together by introducing inorganic pillars which prevent the layers from collapsing at higher temperatures when the swelling agent is evaporated (pillared clays) [154]. A bimodal micro-/mesoporous pore size distribution can thus be obtained. Pillaring can be achieved with a wide variety of reagents including hydroxylaluminum polymers, zirconia hydroxypolymers, silica, and silicate pillars. Cat-

Figure 9. Structures of four representative zeolites and their micropore systems and dimensions [149]

alytically active components may be built in by the pillaring material, e.g., transition metal oxide pillars.

Table 4. Examples of mixed metal oxide catalysts and their applications∗

Catalyst	Active phases	Industrial processes
Copper chromite	$CuCr_2O_4$, CuO	low-temperature CO conversion, oxidations, hydrogenation
Zinc chromite	$ZnCr_2O_4$, ZnO	methanol synthesis (high pressure)
Copper/zinc chromite	$Cu_xZn_{1-x}Cr_2O_4$, CuO	methanol synthesis (low pressure)
Iron molybdate	$Fe(MoO_4)_3$, MoO_3	methanol to formaldehyde
Zinc ferrite	$ZnFe_2O_4$	oxidative dehydrogenation
Chromia – alumina	$Cr_xAl_{2-x}O_3$	dehydrogenation of light alkanes

∗ Adapted from [155]

Mixed metal oxides are multimetal multiphase oxides which typically contain one or more transition metal oxide and exhibit significant chemical and structural complexity [155], [156]. Their detailed characterization is therefore extremely difficult, and structure-property relationships can only be established in exceptional cases. Bulk mixed metal oxide catalysts are widely applied in selective oxidation, oxydehydrogenation, ammoxidation and other redox reactions. Several examples of mixed metal oxides and their application in industrial processes are summarized in Table 4.

Vanadium phosphates (e.g., $VOHPO_4 \cdot 0.5\,H_2O$) are precursors for the so-called *VPO catalysts*, which catalyze ammoxidation reactions and the selective oxidation of *n*-butane to maleic anhydride. It is proposed that the crystalline vanadyl pyrophosphate phase $(VO)_2P_2O_7$ is responsible for the catalytic properties of the VPO system. The vanadium phosphate precursor undergoes transformations in re-

ducing and oxidizing atmospheres, as shown in the following scheme [157]:

As discussed by GRASSELLI [61] effective ammoxidation (and oxidation) catalysts are multifunctional and need several key properties, including active sites which are composed of at least two vicinal oxide species of optimal metal – oxygen bond strengths. Both species must be readily reducible and reoxidizable.

The individual active sites must be spatially isolated from each other (site-isolation concept) to achieve the desired product selectivities. They should either be able to dissociate dioxygen and to incorporate the oxygen atoms into the lattice, or they must be located close to auxiliary reoxidation sites which contain metals having a facile redox couple. These sites are generally distinct from each other. They must, however, be able to communicate with each other electronically and spatially so that electrons, lattice oxygen, and anion vacancies can readily move between them. The lattice must be able to tolerate a certain density of anion vacancies without structural collapse [61]. It is clear that these complex requirements can only be achieved by multicomponent materials.

GRASSELLI [61], [158] has listed three key catalytic functionalities required for effective ammoxidation/oxidation catalysts:

1) An α-H-abstracting component, which may be Bi^{3+}, Sb^{3+}, Te^{4+}, or Se^{4+}.
2) A component that chemisorbs alkene/ammonia and inserts oxygen/nitrogen (Mo^{6+}, Sb^{5+}).
3) A redox couple such as Fe^{2+}/Fe^{3+}, Ce^{3+}/Ce^{4+}, or U^{5+}/U^{6+} to facilitate lattice oxygen transfer between bulk and surface of the solid catalyst.

An empirical correlation was found between the electron configurations of the various metal cations and their respective functionalities [61], [158] as shown in Table 5. This correlation can be used to design efficient catalysts.

Bismuth molybdates are among the most important catalysts for selective oxidation and ammoxidation of hydrocarbons [157], [61]. The phase diagram shown in Figure 10 demonstrates the structural complexity of this class of ternary oxides [159]. The catalytically most important phases lie in the compositional range Bi/Mo atomic ratio between 2/3 and 2/1 and are α-$Bi_2Mo_3O_{12}$, β-$Bi_2Mo_2O_9$, and γ-Bi_2MoO_6. An industrially used Bi molybdate catalyst was optimized in several steps and has the empirical formula $(K,Cs)_a(Ni,Co,Mn)_{9.5}(Fe,Cr)_{2.5}BiMo_{12}O_x$ [61]. This material is supported on 50 % SiO_2 and was subsequently optimized further to give a catalyst with the empirical formula $(K,Cs)_a(Ni,Mg,Mn)_{7.5}(Fe,Cr)_{2.3}Bi_{0.5}Mo_{12}O_x$.

Antimonites are a second important class of ammoxidation catalysts [61], the most important of which are those containing at least one of the elements U, Fe, Sn, Mn, or Ce, which all have multiple oxidation states. Many formulations of catalysts have been proposed over the years. Those of current commercial interest have extremely complex compositions, e.g., $Na_{0-3}(Cu,Mg,Zn,Ni)_{0-4}(V,W)_{0.05-1}Mo_{0.1-2.5}$-$Te_{0.2-5}Fe_{10}Sb_{13-20}O_x$ [61], [160].

Scheelites. Numerous multicomponent oxides adopting the scheelite ($CaWO_4$) structure with the general formula ABO_4 are known [161]. This structure tolerates cation replacements irrespective of valency provided that A is a larger cation than B and that there is charge balance. An additional property of the scheelite structure is that it is often stable with 30 % or more vacancies in the A cation sublattice. As an example, $Pb^{2+}_{1-3x}Bi^{3+}_{2x}\square_x Mo^{6+}O^{2-}_4$, where $\square$ indicates a vacancy in the Bi^{3+} (A cation) sublattice, possesses scheelite structure. The materials are active for selective oxidation of C_3 and C_4 alkenes, which involves formation of allyl species followed by extraction of O^{2-} from the lattice. Replenishment of the created vacancies occurs by oxygen chemisorption at other sites and diffusion of O^{2-} ions within the solid. The introduction of A cation vacancies has a significant effect on allyl formation, and the more open structure which prevails when cation vacancies are present facilitates O^{2-} transport.

Table 5. Electronic structure of some catalytically active elements and their functionalities [158]

α-H abstraction	Alkene chemisorption/O insertion	Redox couple	Example
Bi^{3+} $5d^{10}6s^2 6p^0$	Mo^{6+} $4d^0 5s^0$	Ce^{3+}/Ce^{4+} Fe^{2+}/Fe^{3+}	$Bi_2O_3 \cdot nMoO_3$ $M_a^{2+}M_b^{3+}Bi_xMo_yO_z$
Te^{4+} $4d^{10}5s^2 5p^0$	Mo^{6+} $4d^0 5s^0$	Ce^{3+}/Ce^{4+}	Te_2MoO_7 $(Te_aCe_bMo_v)O_z$
Sb^{3+} $4d^{10}5s^2 5p^0$ U^{5+} $5f^1 6d^0 7s^0$ Se^{4+} $3d^{10}4s^2 4p^0$	Sb^{5+} $5d^0 5s^0$ Sb^{5+} $5s^0 5p^0$ Te^{6+} $5s^0 5p^0$	Fe^{2+}/Fe^{3+} U^{5+}/U^{6+} Fe^{2+}/Fe^{3+}	$Fe_xSb_yO_z$ USb_3O_{10} $Fe_aSe_b^{4+}Te_c^{6+}O_x$

Figure 10. Phase compositions
2/3: $Bi_2O_3 \cdot 3\,MoO_3$; 1/1: $Bi_2O_3 \cdot 2\,MoO_3$; 2/1 (K): $Bi_2O_3 \cdot MoO_3$ (koechlinite); 2/1 (H): $Bi_2O_3 \cdot MoO_3$ (high-temperature form); 3/1 (L): $3\,Bi_2O_3 \cdot 2\,MoO_3$ (low-temperature form); 3/1 (H): $3\,Bi_2O_3 \cdot 2\,MoO_3$ (high-temperature form) [62]

Perovskite is a mineral ($CaTiO_3$) which is the parent solid for a whole family of multicomponent oxides with the general formula ABO_3 [136], [162]. The common feature, which also resembles that of the scheelite-type oxides, is the simultaneous presence of a small, often highly charged, B cation and a large cation A, often having a low charge. The structure also tolerates a wide variety of compositions. As an example, $La^{3+}_{1-x}Sr^{2+}_xY^{3+}O^{2-}_{3-1/2x}$ is active for methane coupling. Other applications of perovskite-type oxides in catalysis are in fuel cells, as catalysts for combustion and for $DeNO_x$ reactions.

Hydrotalcites are another family of solids which tolerate rather flexible compositions [155], [163], [164]. Hydrotalcite is a clay mineral. It is a hydroxycarbonate of Mg and Al of general formula $[Mg_6Al_2(OH)_{16}]CO_3 \cdot 4H_2O$. The compositional flexibility of the hydrotalcite lattice permits the incorporation of many different metal cations and anions to yield solids with the general formula $[M^{2+}_{1-x}M^{3+}_x(OH)]^{x+}(A^{n-})_{x/n} \cdot nH_2O$ ($M^{2+} = Mg^{2+}$, Ni^{2+}, Zn^{2+}, etc.; $M^{3+} = Al^{3+}$, Fe^{3+}, Cr^{3+}, etc.; $A^{n-} = CO_3^{2-}$, SO_4^{2-}, NO_3^-, etc.). Hydrotalcites develop large surface areas and basic properties. They have consequently been applied as solid catalysts for base-catalyzed

reactions for fine-chemicals synthesis, polymerization of alkene oxides, aldol condensation, etc. Hydrotalcite-type phases (and also malachite (rosasite)- and copper zinc hydroxycarbonate (aurichalcite)-type phases) can also be used as precursors for the synthesis of mixed oxides by thermal decomposition, for example, Cu – Zn and Cu – Zn – Cr catalysts [155].

Heteropolyanions are polymeric oxoanions (*polyoxometallates*) formed by condensation of more than two kinds of oxoanions [165], [166]. The amphoteric metals of Groups 5 (V, Nb, Ta) and 6 (Cr, Mo, W) in the +5 and +6 oxidation states, respectively, form weak acids which readily condense to form anions containing several molecules of the acid anhydride. Isopolyacids and their salts contain only one type of acid anhydride. Condensation can also occur with other acids (e.g., phosphoric or silicic) to form heteropolyacids and salts. About 70 elements can act as central heteroatoms in heteropolyanions. The structures of heteropolyanions are classified into several families according to similarities of composition and structure such as, e.g.: Keggin type $XM_{12}O_{40}^{n-}$; Dawson type $X_2M_{18}O_{62}^{n-}$; Anderson type $XM_6O_{24}^{n-}$, where X stands for the heteroatom. The most common structural feature is the Keggin anion, for which the catalytic properties have been studied extensively. Typically the M atoms in catalytic applications are either Mo or W. Heteropoly compounds can be applied as heterogeneous catalysts in their solid state. Their catalytic performance is determined by the primary structure (polyanion), the secondary structure (three-dimensional arrangement of polyanions, counter cations, and water of crystallization, etc.), and the tertiary structure (particle size, pore structure, etc.) [167], [168]. In contrast to conventional heterogeneous catalysts, on which reactions occur at the surface, the reactants are accomodated in the bulk of the secondary structure of heteropoly compounds. Certain heteropolyacids are flexible, and polar molecules are easily absorbed in interstitial positions of the bulk solid, where they form a pseudoliquid phase [167], [168].

Heteropoly compounds develop acidic and oxidizing functions, so that they can be used for acid and redox catalysis. In addition, polyanions are well-defined oxide clusters. Catalyst design is therefore possible at the molecular level. The pseudoliquid provides a unique reaction environment.

Some solid heteropolyacids have high thermal stability and are therefore suitable for vapor-phase reactions at elevated temperatures. The thermal stability of several heteropolyacids decreases in the sequence $H_3PW_{12}O_{40} > H_4SiW_{12}O_{40} > H_3PMo_{12}O_{40} > H_4SiMo_{12}O_{40}$ [167], [168]. It can be enhanced by formation of the appropriate salts [169], [170].

Because of their multifunctionality, heteropolyacids catalyze a wide variety of reactions including hydration and dehydration, condensation, reduction, oxidation, and carbonylation chemistry with Keggin-type anions of V, Mo [168], [169], [171–173]. A commercially important process, the oxidation of methacrolein, is catalyzed by a Cs salt of $H_4PVMo_{11}O_{40}$. Heteropoly salts with extremely complex compositions have been proposed, e.g., for the oxydehydrogenation of ethane. A Keggin-type molybdophosphoric salt with formula $K_2P_{1.2}MO_{10}W_1Sb_1Fe_1Cr_{0.5}Ce_{0.75}O_n$ was found to be the most efficient among the tested solids in terms of activity, selectivity, and stability [174].

3.1.2. Metals and Metal Alloys

Metals and metal alloys are used as bulk, unsupported catalysts in only a few cases. *Metal gauzes* or *grids* are used as bulk catalysts in strongly exothermic reactions which require catalyst beds of small height. A typical example are platinum – rhodium grids used for ammonia oxidation in the nitric acid process [175] and silver grids for the dehydrogenation of methane to formaldehyde.

Skeletal (*Raney-type*) *catalysts*, particularly skeletal nickel catalysts, are technologically important materials [176] which are specifically applied in hydrogenation reactions. However, their application is limited to liquid-phase reactions. They are used in particular for the production of fine chemicals and pharmaceuticals. Skeletal catalysts are prepared by the selective removal of aluminum from Ni – Al alloy particles by leaching with aqueous sodium hydroxide [176]. Besides skeletal Ni, cobalt, copper, platinum, ruthenium, and palladium catalysts have

been prepared, with surface areas between 30 and 100 $m^2 g^{-1}$. One of the advantages of skeletal metal catalysts is that they can be stored in the form of the active metal and therefore require no prereduction prior to use, unlike conventional catalysts, the precursors of which are oxides of the active metal supported on a carrier.

Fused catalysts are particularly used as alloy catalysts. The synthesis from a homogeneous melt by rapid cooling may yield metastable materials with compositions that can otherwise not be achieved [177]. Amorphous metal alloys have also been prepared (metallic glasses) [177], [178].

Oxide materials can also be fused for catalytic applications [177]. Such oxides exhibit a complex and reactive internal interface structure which may be useful either for direct catalytic application in oxidation reactions or in predetermining the micromorphology of resulting catalytic materials when the oxide is the catalyst precursor. The prototype of such a catalyst is the multiply promoted iron oxide precursor of catalysts used for ammonia synthesis [45], [179].

3.1.3. Carbides and Nitrides [45], [180]

Monometallic carbides and nitrides of early transition metals often adopt simple crystal structures in which the metal atoms are arranged in cubic close-packed (ccp), hexagonal close-packed (hcp), or simple hexagonal (hex) arrays. C and N atoms occupy interstitial positions between metal atoms (interstitial alloys). The materials have unique properties in terms of melting point (> 3300 K), hardness (> 2000 kg mm^{-2}), and strength ($> 3 \times 10^5$ MPa). Their physical properties resemble those of ceramic materials, although their electronic and magnetic properties are typical of metals. Carbon in the carbides donates electrons to the d band of the metal, thus making the electronic characteristics of, e.g., tungsten and molybdenum resemble more closely those of the platinum group metals.

Bulk carbides and nitrides, e.g., of tungsten and molybdenum, can be prepared with surface areas between 100 and 400 $m^2 g^{-1}$ by advanced synthetic procedures [180], so that they can be applied as bulk catalysts. They catalyze a variety of reactions for which noble metals are still preferentially used. Carbides and nitrides are exceptionally good hydrogenation catalysts, and they are active in hydrazine decomposition. Carbides of tungsten and molybdenum are also highly active for methane reforming, Fischer – Tropsch synthesis of hydrocarbons and alcohols, and hydrodesulfurization, and the nitrides are active for ammonia synthesis and hydrodenitrogenation [179]. The catalytic properties of carbides can be fine tuned by treatment with oxygen, which leads to the formation of oxycarbides [184]. While clean molybdenum carbide is an excellent catalyst for C – N bond cleavage (cracking of hydrocarbons), molybdenum oxidecarbide is selective for skeletal isomerization [184].

In conclusion, carbides and nitrides, especially those of tungsten and molybdenum, may well be considered as future substitutes for platinum and other metals of Groups 8 – 10 as catalysts.

3.1.4. Carbons [185]

Although carbons are frequently used as catalyst supports, they may also be used as catalysts in their own right [186], [187]. Carbons exist in a variety of thermodynamic phases (allotropes of carbon) and metastable structures, which are often ill-defined (see also → Carbon). The surface chemistry of carbons is rather complex [119], [185]. Carbon surfaces may contain a variety of functional groups, particularly those containing oxygen, depending on the provenience and pretreatment of the carbon. At a single adsorption site several chemically inequivalent types of heteroatom bonds may form. Strong interactions between surface functional groups further complicate the variety of surface chemical structures derived for the most important carbon – oxygen system. Two functions of the carbon surface act simultaneously during a catalytic reaction. Firstly, the reactants are chemisorbed selectively on the carbon surface by ion exchange via oxygen functional groups or directly by dispersion forces involving the graphite valence-electron system. The second function is the production of atomic oxygen occurring on the graphene basal faces of all sp^2 carbon materials [185].

Carbon can already be catalytically active under ambient conditions and in aqueous media. Therefore efforts have been made to apply carbons as catalysts in condensed phases. Its appli-

cation in the gas phase under oxidizing conditions is severely limited by its tendency to irreversible oxidation.

Catalytic applications of carbons include the oxidation of sulfurous to sulfuric acid, the selective oxidation of hydrogen sulfide to sulfur with oxygen in the gas phase at ca. 400 K, the reaction between phosgene and formaldehyde, and the selective oxidation of creatinine by air in physiological environments.

A potential technological application of carbon catalysts involves the catalytic removal of NO by carbon [185].

Recently, carbon nanotubes [185] find significant interest as catalysts and catalyst supports.

3.1.5. Ion-Exchange Resins and Ionomers

Ion-exchange resins (→ Ion Exchangers) are strongly acidic organic polymers which are produced by suspension copolymerization of styrene with divinylbenzene and subsequent sulfonation of the cross-linked polymer matrix [188]. This matrix is insoluble in water and organic solvents. Suspension polymerization yields spherical beads which have different diameters in the range 0.3 – 1.25 mm. The Gaussian size distribution of the beads can be influenced by the polymerization parameters.

A network of micropores is produced during the copolymerization reaction. The pore size is inversely proportional to the amount of cross-linking agent. In the presence of inert solvents such as isoalkanes during the polymerization, which dissolve the reactive monomers and precipitate the resulting polymers, beads with an open spongelike structure and freely accessible inner surface are obtained. The matrix is then a conglomerate of microspheres which are interconnected by cavities or macropores. Macroporous resins are characterized by micropores of 0.5 – 2 nm and macropores of 20 – 60 nm, depending on the degree of cross-linking.

Strongly acidic polymeric resins are thermally stable at temperatures below 390 – 400 K. Above 400 K, sulfonic acid groups are split off and a decrease in catalytic activity results.

Industrially, acidic resins are used in the production of methyl *tert*-butyl ether [189].

The ionomer *Nafion* is a perfluorinated polymer containing pendant sulfonic acid groups which is considered to develop superacidic properties. It can be used as a solid acid catalyst for reactions such as alkylation, isomerization, and acylation [190].

3.1.6. Molecularly Imprinted Catalysts [191]

Molecular imprinting permits heterogeneous *supramolecular catalysis* to be performed on surfaces of organic or inorganic materials with substrate recognition. Heterogeneous catalysts with substrate specificity based on molecular recognition require a material having a shape- and size-selective footprint on the surface or in the bulk. The stabilization of transition states by imprinting their features into cavities or adsorption sites by using stable transition-state analogues as templates is of particular interest.

Imprinted materials can be prepared on the basis of Al^{3+}-doped silica gel [192] and of cross-linked polymers [193], [194]. Chiral molecular footprint cavities have also been designed and imprinted on the surface of Al^{3+}-doped silica gel by using chiral template molecules.

When transition-state or reaction-intermediate analogues are used as templates for molecular imprinting, specific adsorption sites are created. Such molecular footprints on silica gel consist of a Lewis site and structures complementary to the template molecules. These structures can stabilize a reacting species in the transition state and lower the activation energy of the reaction, thus mimicking active sites of natural enzymes and catalytic antibodies.

Although this approach seems to have a high potential for heterogeneous catalysis, the real application of imprinted materials as catalysts still remains to be demonstrated.

3.1.7. Metal Salts

Although salts can be environmentally harmful, they are still used as catalysts in some technologically important processes. $FeCl_3 - CuCl_2$ is a catalyst for chlorobenzene production, and $AlCl_3$ is still used for ethylbenzene synthesis and *n*-butane isomerization.

3.2. Supported Catalysts

Supported catalysts play a significant role in many industrial processes. The support provides high surface area and stabilizes the dispersion of the active component (e.g., metals supported on oxides). Active phase – support interactions, which are dictated by the surface chemistry of the support for a given active phase, are responsible for the dispersion and the chemical state of the latter. Although supports are often considered to be inert, this is not generally the case. Supports may actively interfere with the catalytic process. Typical examples for the active interplay between support and active phase are bifunctional catalysts such as highly dispersed noble metals supported on the surface of an acidic carrier.

To achieve the high surface areas and stabilize the highly disperse active phase, supports are typically porous materials having high thermostability. For application in industrial processes they must also be stable towards the feed and they must have a sufficient mechanical strength.

3.2.1. Supports

Many of the bulk materials described in Section 3.1 may also function as supports. The most frequently used supports are *binary oxides* including transitional aluminas, α-Al_2O_3, SiO_2, MCM-41, TiO_2 (anatase), ZrO_2 (tetragonal), MgO etc., and ternary oxides including amorphous $SiO_2 - Al_2O_3$ and zeolites. Additional potential catalyst supports are aluminophosphates, mullite, kieselguhr, bauxite, and calcium aluminate. *Carbons* in various forms (charcoal, activated carbon) can be applied as supports unless oxygen is required in the feed at high temperatures. Table 6 summarizes important properties of typical oxide and carbon supports.

Silicon carbide, SiC, can also be used as a catalyst support with high thermal stability and mechanical strength [182]. SiC can be prepared with porous structure and high surface area by biotemplating [195]. This procedure yields ceramic composite materials with biomorphic microstructures. Biological carbon preforms are derived from different wood structures by high-temperature pyrolysis (1100 – 2100 K) and used as templates for infiltration with gaseous or liquid Si to form SiC and SiSiC ceramics. During high-temperature processing the microstructural details of the bioorganic preforms are retained, and cellular ceramic composites with unidirectional porous morphologies and anisotropic mechanical properties can be obtained. These materials show low density, high specific strength, and excellent high-temperature stability. Although they have not yet found application in catalysis, the low-weight materials may well be advantageous supports for high-temperature catalysis processes.

Table 6. Properties of typical catalyst supports

Support	Crystallographic phases	Properties/applications
Al_2O_3	mostly α and γ	SA up to 400; thermally stable three-way cat., steam reforming and many other cats.
SiO_2	amorphous	SA up to 1000; thermally stable; hydrogenation and other cats.
Carbon	amorphous	SA up to 1000; unstable in oxid. environm., hydrogenation cats.
TiO_2	anatase, rutile	SA up to 150; limited thermal stability; SCR cats.
MgO	fcc	SA up to 200; rehydration may be problematic; steam reforming cat.
Zeolites	various (faujasites, ZSM-5)	Highly defined pore system; shape selective; bifunctional cats.
Silica/alumina	amorphous	SA up to 800; medium strong acid sites; dehydrogenation cats.; bifunctional catalysts.

SA = surface area in m^2/g

Monolithic supports with unidirectional macrochannels are used in automotive emission control catalysts (→ Automotive Exhaust Control) where the pressure drop has to be minimized [196]. The channel walls are nonporous or may contain macropores. For the above application the monoliths must have high mechanical strength and low thermal expansion coefficients to give sufficient thermal shock resistance. Therefore, the preferred materials of

monolith structures are ceramics (cordierite) or high-quality corrosion-resistant steel. Cordierite is a natural aluminosilicate ($2\,MgO \cdot 2\,Al_2O_3 \cdot 5\,SiO_2$). The accessible surface area of these materials corresponds closely to the geometric surface area of the channels. High surface area is created by depositing a layer of a mixture of up to 20 different inorganic oxides, which include transitional aluminas as a common constituent. This so-called *washcoat* develops internal surface areas of 50 to 300 m^2/g [197], [198].

Silica, *MCM-41*, and *polymers* can be functionalized for application as supports for the preparation of immobilized or hybrid catalysts [119], [122], [199–205]. The functional groups may serve as anchoring sites (surface bound ligands) for complexes and organometallic compounds. Chiral groups can be introduced for the preparation of enantioselective catalysts (see Section 3.2.6).

3.2.2. Supported Metal Oxide Catalysts

Supported metal oxide catalysts consist of at least one active metal oxide component dispersed on the surface of an oxide support [49], [206], [207]. The active oxides are often transition metal oxides, while the support oxides typically include transitional aluminas (preferentially γ-Al_2O_3), SiO_2, TiO_2 (anatase), ZrO_2 (tetragonal), and carbons.

Supported vanadia catalysts are extremely versatile oxidation catalysts. V_2O_5/TiO_2 is used for the selective oxidation of *o*-xylene to phthalic anhydride [208], [209] and for the ammoxidation of alkyl aromatics to aromatic nitriles [209]. The latter reaction is also catalyzed by V_2O_5/Al_2O_3 [209]. The selective catalytic reduction (SCR) of NO_x emissions with NH_3 in tail gas from stationary power plants is a major application of $V_2O_5-MoO_3-TiO_2$ and $V_2O_5-WO_3-TiO_2$ [210], [211]. $MoO_3-Al_2O_3$ and $WO_3-Al_2O_3$ (promoted by oxides of cobalt or nickel) are the oxide precursors for sulfided catalysts (see Section 3.2.5) for hydrotreating of petroleum (hydrodesulfurization, hydrodenitrogenation, hydrocracking) [46, 212, 213]. WO_3-ZrO_2 develops acidic and redox properties [214], [215]. When promoted with Fe_2O_3 and Pt it can be applied as a highly selective catalyst for the low-temperature isomerization of n-alkanes to isoalkanes [216]. $Re_2O_7-Al_2O_3$ is an efficient metathesis catalyst [217]. $Cr_2O_3-Al_2O_3$ and $Cr_2O_3-ZrO_2$ are catalysts for alkane dehydrogenation and for dehydrocyclization of, e.g., *n*-heptane to toluene [218].

The above-mentioned transition metal oxides have lower surface free energies than the typical support materials [49], [219]. Therefore, they tend to spread out on the support surfaces and form highly dispersed active oxide overlayers. These supported oxide catalysts are thus frequently called *monolayer catalysts*, although the support surface is usually not completely covered, even at loadings equal to or exceeding the theoretical monolayer coverage. This is because most of the active transition metal oxides (particularly those of V, Mo, and W) form three-dimensional islands on the support surface which have structures analogous to molecular polyoxo compounds [49], [206].

3.2.3. Surface-Modified Oxides

The surface properties, that is acidity and basicity, of oxides can be significantly altered by deposition of modifiers. The acid strength of aluminas is strongly enhanced by incorporation of Cl^- into or on the surface. This may occur during impregnation with solutions containing chloride precursors of an active component [115] or by deposition of $AlCl_3$. Chlorinated aluminas are also obtained by surface reaction with CCl_4 [119]. The presence of chlorine plays an important role in catalytic reforming with $Pt-Al_2O_3$ catalysts [47].

Strongly basic materials are obtained by supporting alkali metal compounds on the surface of alumina [220]. Possible catalysts include KNO_3, $KHCO_3$, K_2CO_3, and the hydroxides of the alkali metals supported on alumina.

Sulfation of several oxides, particularly tetragonal ZrO_2, yields strong solid acids, which were originally considered to develop superacidic properties [221–223], because, like tungstated ZrO_2 (see Section 3.2.2), they also catalyze the isomerization of *n*-alkanes to isoalkanes at low temperature.

3.2.4. Supported Metal Catalysts

Metals typically have high surface free energies [219] and therefore a pronounced tendency to reduce their surface areas by particle growth. Therefore, for applications as catalysts they are generally dispersed on high surface area supports, preferentially oxides such as transitional aluminas, with the aim of stabilizing small, nanosized particles under reaction conditions [115], [224]. This can be achieved by some kind of interaction between a metal nanoparticle and the support surface (*metal – support interaction*: MSI), which may influence the electronic properties of the particles relative to the bulk metal. This becomes particularly significant for raft-like particles of monatomic thickness, for which all atoms are surface atoms. Furthermore, the small particles expose increasing numbers of low-coordinate surface metal atoms. Both electronic and geometric effects may influence the catalytic performance of a supported metal catalyst (*particle-size effect*). Aggregation of the nanoparticles leads to deactivation.

Model supported metal catalysts having uniform particle size and structure can be prepared by anchoring molecular carbonyl clusters on support surfaces, followed by decarbonylation [225], [226]. Examples are Ir_4 and Ir_6 clusters on MgO and in zeolite cages.

Bimetallic supported catalysts contain two different metals, which may either be miscible or immiscible as macroscopic bulk alloys. The combination of an active and an inactive metal [e.g., Ni and Cu (miscible) or Os and Cu (immiscible)] dilutes the active metal on the particle surface. Therefore, the catalytic performance of reactions requiring ensembles of several active metal atoms rather than single isolated atoms is influenced [227], [228]. Selectivities of catalytic processes can thus be optimized. Typically, the surface composition of binary alloys differs from that of the bulk. The component having the lower surface free energy is enriched in the surface layer. For example, Cu is largely enriched at the surface of Cu – Ni alloys, even at the lowest concentration. Also, surface compositions of binary alloys may be altered by the reaction atmosphere.

In industrial application, supported metal catalysts are generally used as macroscopic spheres or cylindrical extrudates. By special impregnation procedures, metal concentration profiles within the pellet can be created in a controlled way. Examples are schematically shown in Figure 11 [115]. The choice of the appropriate concentration profile may be crucial for the selectivity of a process because of the interplay between transport and reaction in the porous mass of the pellet. For example for the selective hydrogenation of ethyne impurities to ethene in a feed of ethene, eggshell profiles are preferred.

Figure 11. The four main categories of macroscopic distribution of a metal within a support

Applications of supported metal catalysts, such as noble (Pt, Pd, Rh) or nonnoble (Ru, Ni, Fe, Co) metals supported on Al_2O_3, SiO_2, or active carbon include hydrogenation and dehydrogenation reactions. Ag on Al_2O_3 is used for ethene epoxidation. Supported Au catalysts are active for low-temperature Co oxidation. Multimetal catalysts Pt – Rh – Pd on Al_2O_3 modified by CeO_2 as oxygen storage component are used on a large scale in three-way car exhaust catalysts [198]. Pt supported on chlorinated Al_2O_3 is the bifunctional catalyst used for catalytic reforming, isomerization of petroleum fractions, etc.

Modification of supported Pt catalysts by cinchona additives yields catalysts for the enantioselective hydrogenation of α-ketoesters [229].

3.2.5. Supported Sulfide Catalysts

Sulfided catalysts of Mo and W supported on γ-Al_2O_3 or active carbons are obtained by sulfidation of oxide precursors (supported MoO_3 or WO_3; see Section 3.2.2) in a stream of H_2/H_2S. They are typically promoted with Co or Ni and serve (in large tonnage) for hydrotreating processes of crude oil, including hydrodesulfurization (HDS) [46], [212], [213], hydrodenitrogenation HDN [213], and hydrodemetalation HDM [230]. Currently, the CoMoS and NiMoS models are most accepted for describing the active phase. These phases consist of a single MoS_2 layer or stacks of MoS_2 layers in which

the promotor atoms are coordinated to edges [46], [213], as shown in Figure 12. This figure also indicates that Co may simultaneously be present as Co_9S_8 and as a solid solution in the Al_2O_3 support matrix. It is inferred that the catalytic activity of the MoS_2 layers is related to the creation of sulfur vacancies at the edges of MoS_2 platelets. These vacancies have recently been visualized on MoS_2 crystallites by scanning tunneling microscopy (STM) [231].

Figure 12. Three forms of Co present in sulfided $Co-Mo/Al_2O_3$ catalysts: as sites on the MoS_2 edges (the so-called Co – Mo – S phase), as segregated Co_9S_8, and as Co^{2+} ions in the support lattice.

3.2.6. Hybrid Catalysts [199], [201], [202], [204], [205]

Hybrid catalysts combine homogeneous and heterogeneous catalytic transformations. The goal of the approach is to combine the positive aspects of homogeneous catalysts or enzymes in terms of activity, selectivity, and variability of steric and electronic properties by, e.g., the appropriate choice of ligands (including chiral ligands [232]) with the advantages of heterogeneous catalysts such as ease of separation and recovery of the catalyst. This can be achieved by *immobilization* (*heterogenization*) of active metal complexes, organometallic compounds, or enzymes on a solid support.

There are several routes for the synthesis of immobilized homogeneous catalysts:

1) Anchoring the catalytically active species via covalent bonds on the surface of suitable inorganic or organic supports such as SiO_2, mesoporous MCM-41, zeolites, polystyrenes, and styrene – divinylbenzene copolymers [199–201], [205]. The polymerization or copolymerization of suitably functionalized monomeric metal complexes is also known.
2) Chemical fixation by ionic bonding using ion exchange.
3) Deposition of active species on surfaces of porous materials by chemi- or physisorption, or chemical vapor deposition (CVD). The "ship-in-bottle" principle belongs to this synthetic route, but is treated separately in Section 3.2.7.
4) Moleculary defined surface organometallic chemistry may also yield immobilized active organometallic species.

The reagents for covalent bonding on siliceous materials (SiO_2, MCM-41) are often alkoxy- or chlorosilanes which are anchored to the surface by condensation reactions with surface hydroxyl groups [199–201], [205]. Functional groups thus created on the surface can include phosphines, amines etc., which serve as anchored ligands for active species that undergo ligand-exchange reactions. Careful control of the density of functional groups leads to spatial separation of active complexes (site isolation) and thus helps to avoid undesired side reactions [233].

Immobilized enzymes (→ Immobilized Biocatalysts) are frequently used in biocatalysis and in organic synthesis. The synthesis and catalytic performance of this class of heterogenized materials is discussed in several review articles [205], [234].

Dendrimers [235] which are functionalized at the ends of the dendritic arms can be used for immobilization of metal complexes. A catalytic effect is thus generated at the periphery of the dendrimer. Dendrimers with core functionalities have also been synthesized. The resemblance of the produced structures to prosthetic groups in enzymes led to the introduction of the word *dendrizymes* [236]. Dendrimers have found application, e.g., in membrane reactors.

Immobilized homogeneous catalysts are used for selective oxidation reactions, for hydrogenation, and for C – C coupling reactions. They have proved very efficient in asymmetric synthesis [201], [204], [237].

Special processes with immobilized catalysts are *supported (solid) liquid-phase catalysis* (SLPC) [238] and *supported (solid) aqueous-phase catalysis* (SAPC) [239]. In SLPC a solution of the homogeneous catalyst in a high-boiling solvent is introduced into the pore vol-

Figure 13. Schematic representation of SAP catalysis

ume of a porous support by capillary forces, and the reactants pass the catalyst in the gas phase. For example, the active phase – a mixture of vanadium pentoxide with alkali metal sulfates or pyrosulfates – is present as a melt in the pores of the SiO_2 support under the working conditions of the oxidation of SO_2 [240]. In SAPC hydrophobic organic reactants are converted in the liquid phase. The catalyst consists of a thin film of water on the surface of a support (e.g., porous SiO_2) and contains an active hydrophilic organometallic complex [239]. The reaction takes place at the interface between the water film and an organic liquid phase containing the hydrophobic reactant. The nature of these catalyst systems is schematically shown in Figure 13.

3.2.7. Ship-in-a-Bottle Catalysts [241]

Metal complexes which are physically entrapped in the confined spaces of zeolite cages (*confined catalysts*) are known as *ship-in-a-bottle catalysts* or *tea-bag catalysts*. The entrapped complexes are assumed to retain many of their solution properties. The catalytic performance can be modified in a synergistic manner by shape selectivity, the electrostatic environment, and the acid-base properties of the zeolite host. Ligands for metal centers in the zeolite cages include ethylenediamine, dimethylglyoxime, various Schiff bases, phthalocyanines, and porphyrins [241], [242]. The entrapped complexes can be obtained via three principal routers [241]:

1) Reaction of the preformed flexible ligand with transition metal previously introduced into the zeolite cages (flexible ligand method). The synthesis of a zeolite entrapped metal-salen complex is schematically shown in Figure 14.
2) Assembling the ligand from smaller species inside the zeolite cavities (ship-in-a-bottle

technique). For example, the synthesis of a zeolite-entrapped metal phthalocyanine is schematically shown in Figure 15.

3) Synthesis of the zeolite structure around the preformed transition metal complex (zeolite synthesis technique).

The success of ship-in-a-bottle catalysts in catalytic processes has still to be demonstrated.

Zeolite-encapsulated complexes have also been suggested as model compounds for mimicking enzymes. These zeolite-based enzyme mimics are called *zeozymes* to describe a catalytic system, in which the zeolite replaces the protein mantle of the enzyme, and the entrapped metal complex mimics the active site of the enzyme (e.g., an iron porphyrin) [243].

Host – guest supramolecular compounds may also be mentioned in this context [191], [244].

3.2.8. Polymerization Catalysts

Ziegler – Natta (→ Polyolefins, Chap. 1.3.2.2.) catalysts are mixtures of solid and liquid compounds containing a transition metal such as Ti or V [245], [246]. $TiCl_4$ combined with $Al(C_2H_5)_3$ or other alkylaluminum compounds were found to be active for olefin polymerization. More active catalysts were produced commercially by supporting the $TiCl_4$ on solid $MgCl_2$, SiO_2 or Al_2O_3 to increase the amount of active titanium. Currently, Ziegler – Natta catalysts are produced by ball milling $MgCl_2$ with about 5 % of $TiCl_4$, and the cocatalyst is $Al(C_2H_5)_3$.

The *Phillips catalyst* (→ Polyolefins, Chap. 1.3.2.1.) consists of hexavalent surface chromate on high surface area silicate supports. Cr^{6+} is reduced by ethylene or other hydrocarbons, probably to Cr^{2+} and Cr^{3+}, the catalytically active species [245], [246].

More recently, so-called single-site catalysts using metallocenes as active species were developed (→ Metallocenes, → Polyolefins, Chap. 1.3.2.3.) [246], [247]. The activity of these materials is dramatically enhanced by activation with methylaluminoxane (MAO), obtained by incomplete hydrolysis of $Al(CH_3)_3$, the catalytic performance of which is significantly more versatile than that of the classical Ziegler – Natta or Phillips catalysts. Activities and the nature of the polymeric product can be taylored by the choice of the metal and ligands.

4. Production of Heterogeneous Catalysts

The develompent of heterogeneously catalyzed reactions for the production of chemicals initiated the preparation of the required catalysts on a technical scale. Up to the end of World War II, solid catalysts were produced predominantly in process companies such as IG Farben and BASF in Germany, and Standard Oil Company and UOP in the USA [248], [249]. About ten years later some independent catalyst producing companies were founded in the USA, Western Europe, and Japan [248]. At present more than 15 international companies [248], [250] are producing solid catalysts on multitonne scale; for example:

- Engelhard Corp. (incl. Harshaw Catalyst)
- ICI Catalysts and ICI Catalco
- Davison Chemicals and Grace
- SÜD-Chemie Catalyst Group (incl. UCI, Houdry, Prototec in the USA, NGC, CCIFE in Japan, UCIL in India and AFCAT, SYNCAT in South Africa)
- UOP and Katalystiks
- BASF
- Monsanto
- Shell and Criterion Catalysts
- Akzo Chemicals
- Johnson Matthey
- Haldor Topsøe
- Calsicat
- Degussa
- Nippon Shokubai
- Nikki Chemical

In 1991 the catalyst world market achieved a turnover of about $\$ 6 \times 10^9$ [248], [249], [251], grew to $\$ 7.3 \times 10^9$ in 1994, and reached $\$ (8-9) \times 10^9$ in 1996.

Approximately 24 – 28 % of produced catalysts were sold to the chemical industry and 38 – 42 % to petrochemical companies including refineries. 28 – 32 % of solid catalysts were used in environmental protection, and 3 – 5 % in the production of pharmaceuticals [248], [251].

Figure 14. Synthesis of zeolite-entrapped metal salen complexes by the flexible ligand method

Figure 15. Ship-in-a-bottle synthesis of zeolite-encaged metal phthalocyanines

The catalytic properties of solid catalysts are strongly affected by the preparation method, production conditions, and quality of source materials. Therefore, it is necessary to control each production step and the physical or mechanical properties of all intermediates. To attain a better reproducibility of catalyst production, batch procedures were mainly replaced by continuous operations, such as precipitation, filtration, drying, calcination, and forming.

Automatization of various operations and computer control of different equipments were installed in catalyst production lines [248]. Recently, SPC (statistic process control) and QA (quality assurance) were integrated into the catalyst production process. Some companies, especially in Western Europe and in the USA, produce solid catalysts according to ISO Standard which guarantees a standard catalyst quality to the customer [248], [252].

Catalysts applied in several industrial processes can be subdivided into the following categories:

- Unsupported (bulk) catalysts
- Supported catalysts
- Skeletal catalysts

4.1. Unsupported Catalysts

Unsupported catalysts represent a large category and are applied in numerous industrial processes. Various preparation methods were adopted in the past decades in the commercial production of unsupported catalyst, such as mechanical treatment or fusion of catalyst components, precipitation, coprecipitation, flame hydrolysis, and hydrothermal synthesis [177], [250], [253–257].

Mechanical treatment, for example, mixing, milling, or kneading of catalytic active materials or their precursors with promoters, structure stabilizers, or pore-forming agents, is one of the simplest preparation methods [250], [253–255]. In some cases, however, the required intimate contact of catalyst components could not

be achieved and therefore the activity, selectivity, or thermal stability of catalysts prepared in this way was lower than of those prepared by other methods. However, recent improvements in the efficiency of various aggregates for the mechanical treatment of solids resulted in activity enhancement. An important advantage of these methods is that formation of wastewater is avoided.

Industrial catalysts produced by mechanical treatment are summarized in Table 7.

Table 7. Unsupported catalysts prepared by mechanical treatment (MT) or by fusion (F)

Catalyst∗	Preparation method	Application
Fe_2O_3(K, Cr, Ce, Mo)	MT	ethylbenzene dehydrogenation (styrene production)
Fe_2O_3(K)	MT	Fischer – Tropsch synthesis
$ZnO - Cr_2O_3$	MT	hydrogenation of carbonyl compounds
Fe_3O_4(K, Al, Ca, Mg)	F	NH_3 synthesis
$V_2O_5 - K_2S_2O_7$	F	SO_2 oxidation (H_2SO_4 production)
Pt/Rh grid	F	NH_3 oxidation (HNO_3 production)

∗ Elements in parentheses are promoters.

Fusion of components or precursors is used for the production a small group of unsupported catalysts. The fusion process [177] permits the synthesis of alloys consisting of elements which do not mix in solution or in the solid state. However, preparation of unsupported catalysts by fusion is an energy-consuming and quite expensive process.

The most important application of this method is the production of ammonia synthesis catalysts based on the fusion of magnetite (Fe_3O_4) with promoters such as oxides of K, Al, Ca, and Mg [177]. Another example is the preparation of SO_2 oxidation catalysts by fusion of V_2O_5 with K pyrosulfate ($K_2S_2O_7$) [177]. Some producers incorporate Cs oxide as an activity promoter in this catalyst.

Quite recently, amorphous alloys composed, e.g., of Pd and Zr, so-called *metallic glasses* were found to be active in catalytic oxidations [177], [178].

Industrial catalysts produced by the fusion process are listed in Table 7.

Precipitation and coprecipitation are the most frequently applied methods for the preparation of unsupported catalysts or catalyst supports [250], [253–257]. However, both methods have the major disadvantage of forming large volumes of salt-containing solutions in the precipitation stage and in washing the precipitate.

Source materials are mainly metal salts, such as sulfates, chlorides, and nitrates. Acetates, formates, or oxalates are used in some cases. In industrial practice nitrates or sulfates are preferred. Basic precipitation agents on an industrial scale are hydroxides, carbonates, and hydroxocarbonates of sodium, potassium, or ammonium.

Then alkali metal nitrates or sulfates formed as precipitation by-products must be washed out of the precipitate. Thermally decomposable anions, e.g., carbonates, carboxylates, and cations such as NH_4^+, are especially favored in catalyst production.

Coprecipitation of two or more metal cations is a suitable operation for the homogeneous dispersion of the corresponding oxides, especially if the catalyst precursors have a defined crystalline structure, for example, $Cu(OH)NH_4CrO_4$ or $Ni_6Al_2(OH)_{16}CO_3$. After thermal treatment, binary oxides such as $CuO - Cr_2O_3$ and $NiO - Al_2O_3$ are formed [250], [253–257].

Precipitation and coprecipitation can be carried out in batch or continuous operations.

If the metal salt solution is placed in the precipitation vessel and the precipitating agent is added, then the pH changes continuously during the precipitation. Coprecipitation should be carried out in the reverse manner (addition of the metal salt solution to the precipitation agent) to avoid sequential precipitation of two or three metal species.

If the metal salt solution and the precipitating agent are simultaneously introduced into the precipitation vessel, then it is possible to keep the pH constant. However, the residence time of the precipitate in the vessel changes continuously.

Finally, if the metal salt solution and the precipitating agent are continuously introduced in the precipitation vessel, and the reaction products are removed continuously, then pH and res-

idence time can be kept constant [250], [253–257].

Besides pH and residence time, other precipitation parameters, such as temperature, agitation, and concentration of starting solutions, affect the properties of the precipitate. The choice of anions, the purity of raw material, and the use of various additives also play an important role [250], [253–257].

In general, highly concentrated solutions, low temperatures and short ageing times result in finely crystalline or amorphous materials which are difficult to wash and filter. Lower concentrations of the solutions, higher temperatures, and extended ageing provide coarse crystalline precipitates which are easier to purify and separate [250], [253–257].

The industrial production of precipitated catalysts usually involves the following steps:

- Preparation of metal salt solution and of precipitating agent (dissolution, filtration)
- Precipitation
- Ageing of the precipitate
- Washing of the precipitate by decantation
- Filtration
- Washing of the filtercake (spray drying)
- Drying
- Calcining
- Shaping
- Activation

Operations such as filtration, drying, calcination etc. are discussed in Section 4.4.

Typical unsupported industrial catalysts produced by precipitation or coprecipitation are compiled in Table 8.

The sol – gel process [258] involves the formation of a sol, followed by the creation of a gel. A sol (liquid suspension of solid particles smaller than 1 µm) is obtained by the hydrolysis and partial condensation of an inorganic salt or a metal alkoxide. Further condensation of sol particles into a three-dimensional network results in the formation of a gel. The porosity and the strength of the gel are strongly affected by conditions of its formation. For example, slow coagulation, elevated temperature, or hydrothermal posttreatment increase the crystalline fraction of the gel.

Alumina and silica can be produced from sodium aluminate or sodium silicate by treatment with nitric, hydrochloric, or sulfuric acid. In this process, first sols and then gels are formed. Washing the sodium from the gels is essential [255], [256], [258].

Table 8. Catalysts (their precursors) or supports prepared by precipitation or coprecipitation

Catalysts (precursors) or supports	Source materials	Application
Alumina	Na aluminate, HNO_3	support, dehydration, Claus process
Silica	Na silicate (water glass), H_2SO_4	support
Fe_2O_3	$Fe(NO_3)_3$, NH_4OH	ethylbenzene dehydrogenation (styrene production)
TiO_2	Fe titanate, titanyl sulfate, NaOH	support, Claus process, NO_x reduction
$CuO-ZnO-(Al_2O_3)$	Cu, Zn, (Al) nitrates, Na_2CO_3	LTS, methanol synthesis
Fe molybdate	$Fe(NO_3)_3$, $(NH_4)_2MoO_4$, NH_4OH	methanol oxidation to formaldehyde
Vanadyl phosphate	vanadyl sulfate, $NaHPO_4$	butane oxidation to maleic acid anhydride
$NiO-Al_2O_3$	Ni, Al nitrates, Na_2CO_3	hydrogenation of aromatics
$NiO-SiO_2$	Ni nitrate, Na silicate, Na_2CO_3	hydrogenation of aromatics

Spherical silica or silica-alumina gels are produced directly by injecting drops of a gelling mixture into oil at a proper rate to allow setting of the gel. To avoid bursting during drying, the gel beads are washed to reduce the salt content ($NaNO_3$, NaCl, or Na_2SO_4). Finally, the beads are dried and calcined [255], [256].

Based on the sol – gel process, high-purity materials such as alumina, TiO_2, ZrO_2 are produced on an industrial scale. Raw materials are the corresponding metal alkoxides, e.g., $Al(C_{12}-C_{18}$ alkoxide$)_3$ and $Ti(n\text{-}C_4H_9O)_4$ [258].

Flame Hydrolysis. In flame hydrolysis [259] a mixture of the catalyst or support precursor, hydrogen, and air is fed into the flame of a continuously operating reactor. Precursors (mainly chlorides such as $AlCl_3$, $SiCl_4$, $TiCl_4$ or $SnCl_4$) are hydrolyzed by steam (formed by H_2 oxidation). The products of flame hydro1ysis are oxides. More than 100 000 t/a of so-called fumed silica, alumina, or titania are produced

by Degussa, Wacker (both Germany), and Cabot (USA).

Thermal decomposition of metal – inorganic or metal – organic catalyst precursors is sometimes used in industrial catalyst production. For example, mixtures of Cu- and $Zn(NH_3)_4(HCO_3)_2$ decompose at 370 K to form binary Cu – Zn carbonates, which are transformed during calcination into the corresponding binary oxides, used as low temperature water gas shift catalysts [255].

Industrial production of Cu – Cr oxides (copper chromites), used in the hydrogenation of carbonyl compounds, is based on the thermal decomposition of a basic copper ammonium chromate [$CuNH_4(OH)CrO_4$] at 620 – 670 K [255], [256].

Highly active Ni catalysts for the hydrogenation of fats and oils are obtained by the thermal decomposition of Ni formate [$(HCOO)_2Ni$] at 390 – 420 K. The decomposition is usually carried out in hard fat, which protects Ni against oxidation [255].

Catalysts or supports produced by flame hydrolysis or thermal decomposition of inorganic complexes are summarized in Table 9.

Hydrothermal synthesis [125], [161] is a very important preparation method for zeolites and other molecular sieves.

Currently, the importance of zeolites in industrial catalysis is still increasing. They are used as catalysts or supports not only in petrochemical operations but also in the production of fine chemicals.

In hydrothermal synthesis (see also → Zeolites, Chap. 6.1.) a mixture of silicon and aluminium compounds containing alkali metal cations, water, and in some cases organic compounds (so-called templates) is converted into microporous, crystalline aluminosilicates [256], [260].

Common sources of silicon are colloidal silica, water glass, fumed silica, and silicon alkoxides. Aluminum can be introduced as aluminium hydroxide, metahydroxide, or aluminate salts. Common templates are tetrapropyl- or tetraethylammonium bromides or hydroxides [256], [260].

Hydrothermal synthesis is a complex process consisting of three basic steps: achievement of supersaturation, nucleation, and crystal growth. It is affected by the hydrogel molar composition, a1kalinity, temperature, and time [256], [260].

In general, synthesis is carried out at 360 – 450 K under atmospheric or autogenous water pressure (0.5 – 1 MPa) with residence times of 1 – 6 d. After synthesis, the crystalline product is separated by filtration or centrifugation, washed, dried, and calcined. Sodium-containing zeolites, which are the products of the hydrothermal synthesis, are converted into acidic forms by exchange of sodium ions with the ammonium, followed by thermal treatment [256], [260].

Zeolites used in the industrial catalysis are above all Y zeolite, mordenite, ZSM-5, ZSM-11, and zeolite β [125], [160].

To improve the thermal stability of zeolites, especially of Y zeolite, Al ions are extracted from the lattice by steaming or acid treatment. For example, fluid-cracking catalysts (amorphous aluminosilicates) contain 10 – 50 % of ultrastable Y zeolites [256], [260].

Related to zeolites are other molecular sieves such as aluminum phosphates (AlPO) and silicoaluminum phosphates (SAPO), the importance of which in industrial catalysis is growing. SAPO-11 was applied recently in the isomerization of cyclohexanone oxime to ε-caprolactam, instead of sulfuric acid in a demonstration unit [125].

Other preparation methods include condensation of more than two kinds of oxoanions, such as MoO_4^{2-}, WO_4^{2-}, HPO_4^{2-}, etc. to give heteropolyacids such as $H_3PW_{12}O_{40}$ or $H_3PMo_{12}O_{40}$ [167].

In industrial practice, the source materials are Na_2HPO_4, Na_2WO_4, or Na_2MoO_4 solutions. Hydrolysis and subsequent condensation are carried out with HCl. The heteropolyacids are extracted with organic so1vents. Heteropolyacids are very strong acids with Hammett acidity function $H_o < -8$. They have found industrial application in acid-catalyzed reactions conducted in the liquid phase, such as hydration, esterification, and alkylation. Their activity is evidently higher than that of inorganic acids [167]. Their K or Cs salts are used as catalysts in the selective vapor phase oxidation of propene to acrolein or isobutene to methacrolein [167].

Table 9. Catalysts (their precursors) or supports prepared by sol – gel process (SG), flame hydrolysis (FH), or thermal decomposition (TD) of inorganic metal complexes

Catalyst (precursor) or support	Source material	Preparation method	Application
Alumina (high-purity)	Al alkoxides	hydrolysis, SG	support for noble metals
Alumina (acidic, low bulk density)	$AlCl_3$	FH	support or additive
Silica (low bulk density)	$SiCl_4$	FH	support or additive
TiO_2	$Ti(n\text{-}C_4H_9O)_4$	hydrolysis, SG	support
TiO_2 (low bulk density)	$TiCl_4$	FH	support or additive
CuO – ZnO	Cu, Zn $(NH_3)_4HCO_3$	TD	low-temperature shift, methanol
CuO – Cr_2O_3	$Cu(NH_4)OHCrO_4$	TD	hydrogenation of carbonyl compounds
Ni (kieselguhr)	Ni formate	TD	hydrogenation of fats and oils

Another preparation method is based on the treatment of alumina or aluminosilicate with gases such as HF, HCl, BF_3, $AlCl_3$ to create highly acidic centers. Such catalysts are active in the skeletal isomerization of hydrocarbons, e.g., n-C_4 or n-C_5 [256].

4.2. Supported Catalysts

The main feature of supported catalysts is that the active material forms only a minor part and is deposited on the surface of the support [254–256], [261].

In some cases, the support is more or less inert, e.g., α-alumina, kieselguhr, porous glass, ceramics. In other cases the support takes part in the catalytic reaction, as in the case of bifunctional catalytic systems, e.g., alumina, aluminosilicate, zeolites, etc. [254–256], [261].

Additionally, some supports can alter the catalytic properties of the active phase. This so-called strong metal – support interaction (SMSI) can decrease, for example, the chemisorption capacity of supported metals (Pt – TiO_2) or can hinder the reduction of supported metal oxides (Ni silicate, Ni and Cu aluminates, etc.) [254–256].

4.2.1. Supports

Currently, various industrial supports are available in a multitonne quantities possessing a wide range of surface areas, porosities, shapes, and sizes.

Widely used supports include alumina, silica, kieselguhr, porous glass, aluminosilicates, molecular sieves, activated carbon, titania, zinc oxide, silicates such as cordierite ($2\,MgO \cdot Al_2O_3 \cdot 5\,SiO_2$) and mullite ($3\,Al_2O_3 \cdot 2\,SiO_2$), and Zn and Mg aluminates [254–256].

The supports are produced by specialized producers or directly by catalyst producers. Well known support manufacturers are:

- Davison-Grace (USA, UK, Germany)
- Bayer (Germany)
- Alcoa (USA)
- Kaiser Chem. (USA)
- RWE-DEA, CONDEA (Germany)
- Filtrol-Engelhard (USA)
- Norton (USA)
- Degussa (Germany)
- Cabot Corp. (USA)

In the past, mostly natural supports, e.g., bauxite, pumice and kieselguhr, were used in catalyst production. At present (with the exception of kieselguhr) mainly synthetic supports with "tailored" physical properties are preferred in industrial catalysis.

Because the majority of supports also have catalytic properties (e.g., alumina, aluminosilicates, zeolites) their production methods are described in Section 4.1.

4.2.2. Preparation of Supported Catalysts

The broad application of supported catalysts in industrial catalysis led to the development of numerous preparation methods applicable on a technical scale. Some of these methods are identical with those used in the production of unsupported catalysts, e.g., mechanical treatment, precipitation, thermal decomposition of metal – inorganic or metal – organic complexes and therefore they will be discussed here very briefly.

Mechanical treatment, e.g., kneading of a catalyst precursor with a support is applied, e.g., in the production of kieselguhr-supported Ni (precursor $NiCO_3$) [253], [255], [256]. Also, MoO_3 supported on Al_2O_3 is sometimes produced by this process. However, the distribution of the active phase on the support is in some cases not sufficient [253].

Better results are obtained by the combination of mechanical and thermal treatment which, results in spreading [49] of, e.g., MoO_3 on Al_2O_3 or of V_2O_5 on Al_2O_3 or TiO_2.

Impregnation by pore filling of a carrier with an active phase is a frequently used production method for supported catalysts [115], [253]. The object of this method is to fill pores of the support with a solution of the catalyst precursor, e.g., a metal salt of sufficient concentration to achieve the desired loading. If higher loadings with active phases are required, it is mostly necessary to repeat the impregnation after drying or calcination of the intermediate. Examples of catalysts prepared by the pore filling method are Ni or Co on $Al_2O_3 - MoO_3$, MoO_3 on alumosilicates including zeolites, Ni or Ag on α-alumina, noble metals on active carbon, etc. [250], [253–256].

Adsorption is a very good method to achieve uniform deposition of small amounts of active component on a support. Powders or particles exposed to metal salt solutions adsorb equilibrium quantities of salt ions, in accordance with adsorption isotherms. Adsorption may be either cationic or anionic, depending on the properties of the carrier surface. For example, alumina (depending on the adsorption conditions, mainly on the pH of the solution) adsorbs both cations and anions. Silica weakly adsorbs cations, while magnesia strongly adsorbs anions [250].

Adsorption of $PdCl_2$ from aqueous solution on different aluminas is very fast, and a high equilibrium concentration (ca. 2 wt %) can be obtained. The Pd deposition takes place mainly in an outer shell (egg shell profile) of shaped particles [250], [256].

With $H_2[PtCl_4]$ only 1 wt % Pt loading on alumina is possible owing to from the flat adsorption isotherm [250], [256].

The addition of oxalic, tartaric, and citric acid to the metal salt solution changes the profiles of active component on the carrier. In general, with increasing acid strength the metal ions are forced deeper into the support particles [250].

Ion exchange [115], [250] is very similar to ionic adsorption but involves exchange of ions other than protons. Lower valence ions, such as Na^+ or NH_4^+ can be exchanged with higher valence ions, for example, Ni^{2+} or Pt^{4+}. This method is used mainly in the preparation of metal-containing zeolites, e.g., Ni- or Pd-containing Y zeolites or mordenites used in petroleum-refining processes.

Thermal decomposition of inorganic or organic complexes in the presence of a support. This method is identical with that used in the preparation of unsupported catalysts by thermal decomposition of precursors. Supports can be used either as powder or preshaped. For example, Ni or Co deposited on kieselguhr or silica is produced by this method [255].

Precipitation onto the support is carried out in a similar way as in the case of unsupported catalysts [250], [253], [261]. Supports, mainly as powders, are slurried in the salt solution, and alkali is added. Rapid mixing is essential to avoid precipitation in the bulk.

Uniform precipitation can be achieved by using urea rather than conventional alkalis [261]. An appropriate amount of urea is added to the metal salt – support slurry and the mixture is heated while stirring. At 360 K urea decomposes slowly to NH_3 and CO_2, and precipitation takes place homogeneously over the surface and in pores of the support. This method is called *deposition – precipitation* [261] and is used especially in the production of highly active $Ni - SiO_2$ or $Ni - Al_2O_3$ catalysts.

Coating of nonporous supports [198] with a thin layer of high surface area material is an important step in the production of catalysts for pollution control. Oxides such as Al_2O_3, CeO_2, and ZrO_2 (washcoat) are deposited on monoliths with a honeycomb like structure by dipping into an aqueous slurry containing primary particles (about 20 nm in diameter) of these materials.

Reductive deposition is a preparation method in which especially precious metals are

deposited on the carrier surface by reduction of aqueous metal salts, mainly chlorides or nitrates, with agents such as H_2, Na formate, formaldehyde, and hydrazine. Examples of commercial catalysts produced by this method are precious metals on active carbon, SiO_2 or α-Al_2O_3. Reductive deposition is preferred especially in the case of bimetallic supported catalysts such as Pt – Re or Pd – Rh [262].

Heterogenization of homogeneous catalysts is based on the binding of metal complexes to the surface or entrapment in pores of the inorganic or organic support [205]. Such catalysts are used mainly in stereospecific hydrogenations in the production of fine chemicals or pharmaceuticals.

Enzymes [205] can also be heterogenized. They found industrial application in biochemical processes. A prominent example is the isomerization of glucose to fructose in the production of soft drinks.

4.3. Skeletal Catalysts

Skeletal catalysts, also called porous metals, consist of the metal skeleton remaining after the less noble component of an alloy was removed by leaching with alkali, preferentially NaOH. Skeletal catalysts were discovered 1925 and introduced into chemistry by Raney, and therefore some bear his name, e.g., Raney Ni or Co.

The group of skeletal catalysts [176] includes Ni, Co, Cu, Fe, Pt, Ru, and Pd. The second alloy component can be Al, Si, Zn, or Mg, with Al being used preferentially.

Small amounts of a third metal such as Cr or Mo have been added to the binary alloy as activity promoter.

Ni – Al, Cu – Al, and Co – Al alloys with different grain sizes are commercially available and can be leached out before use. Davison-Grace and Degussa provide finished extremely pyrophoric Ni or Co skeletal catalysts protected by water in commercial quantities. Skeletal Ni found technical application in the hydrogenation of aliphatic or aromatic nitro compounds and nitriles.

4.4. Unit Operations in Catalyst Production

As in other branches of the chemical industry, unit operations have also been established in catalyst production in the past few decades, for example, in operations such as filtration, drying, calcination, reduction and catalyst forming [250], [252], [256]. Continuous operations are favored because of larger throughputs, lower operating costs, and better quality control. Additionally, factors such as environmental pollution and hazards to human health can be minimized more easily.

Filtration, Washing. The main purpose of these operations is to separate precipitates and to remove byproducts and possible impurities. In batch operations mainly plate-and-frame filter presses are used [250], [256]. The washing of the filter cake proceeds in countercurrent to the direction of the filtration.

Continuous vacuum rotary filters are widely used. By changing the speed of the filter drum (covered with filter cloth), the quantity of slurry filtered and the thickness of the filter cake can be varied over a broad range. As the drum rotates, there is a washing phase in which water is sprayed against the moving filter cake. Finally, the filter cake is scraped or blown to remove it from the drum [256].

Another filtration equipment is the centrifuge. However, its application is possible only when the filtered material is grainy or crystalline, e.g., zeolites. Washing can be carried out by introducing washing water into the centrifuge. Centrifuges can operate either in a discontinuous or continuous manner [256].

Drying. Because drying conditions such as rate, temperature, duration, or gas flow rate can change the physical properties of the resulting material, it is important to measure and keep these parameters constant. For example the porosity of precipitated catalysts depends on the drying procedure. The drying of impregnated supports can change the distribution of active components. Their uniform distribution can be obtained only if all the liquid is evaporated spontaneously [250], [253], [256]. Usually, drying proceeds up to 400 K.

For the drying of filter cake, various tools are used, e.g., box furnaces with trays, drum dryers, rotary kilns, and spray dryers [250], [253], [256].

The main problems with drums and rotary dryers are the feeding of the wet filter cake and removal of adhering material from the walls. Because lumps are usually formed in the drying process, the resulting material must pass a granulator equipped with a sieve [256].

Spray dryers provide microspherical materials with a narrow particle-size range. Spray dryers are equipped with a nozz1e or a rotating disk to disperse the watery slurry of the filter cake in a stream of hot air [250], [256], [263].

All the above drying equipment operates in continuous mode.

Small batches of catalyst precursors are dried in box furnaces with trays [253].

For the drying of extrudates, continuously operating belt dryers have found technical application [256].

Calcination The main object of calcination (thermal treatment in oxidizing atmosphere) is to stabilize physical and chemical properties of the catalyst or its precursor. During calcination, thermally unstable compounds (carbonates, hydroxides, or organic compounds) decompose and are usually converted to oxides. During calcination new compounds may be formed, especially if the thermal treatment is carried out at higher temperatures [207]. For example, in the thermal decomposition of Cu or Ni nitrate deposited on alumina, not only CuO or NiO but also Cu or Ni aluminate is additionally formed [207].

Furthermore amorphous material can become crystalline. Various crystalline modifications can undergo reversible or irreversible changes.

Physical and mechanical properties and pore structures can also change. The calcination temperature is usually slightly higher than that of the catalyst operating temperature [250], [253], [256], [263].

For the calcination of powder or granulate, rotary kilns are preferably used [253], [256]. Smaller batches of powdered catalysts are calcined in box or muffle furnaces with trays, as in the case of drying. The gases that are mainly used for heating are in direct contact with the material being calcined [250], [253], [256].

Pellets or extrudates are calcined in belt or tunnel furnaces. The tunnel-type calciner can operate at substantially higher temperatures (close to 1270 – 1470 K) than the belt type (870 – 1070 K). The tunnel calciner is especially suitable for firing ceramic carriers. The material being calcined is taken in boxes or carts which are recycled to the entrance via a continuous chain or belt [256].

Reduction, Activation, and Protection. Reduction, activation, or passivation, is in several cases the last step in catalyst production. These operations are performed by the catalyst producer or in the plant of the client.

For example, in the production of Ni catalysts for the liquid-phase hydrogenation of fats and oils, the reduction of NiO deposited on kieselguhr is carried out exclusively by the catalyst producer. The reduction of powders (50 – 500 μm particle size) is performed on an industrial scale in fluid-bed reactors. The reduced material is pyrophoric and must be protected with a hard fat such as tallow, to make its handling easy and safe. The finished catalyst is supplied in the form of flakes or pastilles [250], [256], [264].

The reduction of metal oxides such as NiO, CuO, CoO, or Fe_2O_3 is carried out with H_2 at elevated temperature (> 470 K) and has two steps. In the first step metal nuclei are formed. In the second, nuclei accumulate to form metal crystallites. The rates of both processes depend on temperature and on the nature of the substrate [250]. Reduction at lower temperatures (< 570 K) provides a narrow distribution of small metal crystallites. Reduction at higher temperatures (> 670 K) gives a broader distribution and larger metal crystallites [250].

Reduction of some oxides, such as those of Cu and Fe, is exothermic and needs to be carried out carefully with H_2 diluted with N_2.

Water, the reduction product, has negative effects on the rate and on the extent of reduction [250]. In industrial practice, where H_2 is recycled, the removal of water by freezing out (below 270 K) and by adsorption on molecular sieve is essential.

To achieve optimal activity, partial reduction of oxidic catalysts is common [250], [265]. For

example, Ni catalysts for fat and oil hydrogenation contain about 50 – 60 wt % of metallic Ni, 45 – 35 wt % NiO, and about 5 wt % Ni silicate.

When the reduction of shaped oxidic catalysts is conducted by the catalyst producer, then the active material is protected either with a high-boiling liquid such as higher aliphatic alcohols or $C_{14} - C_{18}$ paraffins [265] or it is passivated. In this procedure, chemisorbed hydrogen is removed in a gas stream composed of N_2 and about 0.1 – 1.0 vol % of O_2 at ambient temperature. After this treatment catalysts can be handled in air without any precautions [264]. The activity is restored in the client's plant by treatment with H_2 [250].

The activation of hydrotreating catalysts composed of Ni- or Co-promoted $MoO_3 - Al_2O_3$ is carried out with H_2 containing 10 vol % of H_2S [207]. In the past, this activation was performed exclusively in the hydrodesulfurization plants. However, presulfiding at catalyst producers is becoming more common [250].

Mainly electrical or gas-heated shaft reactors are used for the reduction of extrudates, spheres, or pellets in plants of catalyst producers.

Catalyst Forming. The size and shape of catalyst particles depend on the nature of the reaction and on the type of applied reactor.

Reactions in the *liquid phase* require small particles or even powders (50 – 200 µm). Such materials are made by grinding of a dried or calcined precursor, e.g., filter cake, using granulators equipped with sieves to give uniform particle size [250], [256], [263], [265].

Catalysts for *fluidized bed reactors* (0.05 – 0.25 mm) are usually made by spray drying or by cooling molten material droplets (V_2O_5) in an air stream [250], [256], [263].

Spheres consiting of Al_2O_3, SiO_2, or aluminosilicate with 3 – 9 mm diameter are used preferentially as a support for catalysts in *moving-bed* or *ebullating-bed reactors*. They are produced by the so-called oil-drop method (see Section 4.1). Spheres prepared in this way possess sufficient abrasion resistance [250], [256], [263].

Another method for producing spheres is based on agglomeration of powder by moistening on a rotating disk (spherudizer) [250], [256], [263]. As the spheres reach the desired diameter they are removed automatically and transported to the dryer and calciner. Such spheres are suitable for *fixed bed reactors*.

Other methods for forming spherical particles include tumbling short, freshly extruded cylinders in a rotating drum [256].

In the briquetting technique, the plastic mixture of catalyst powder with a binder is fed between two rotating rolls provided with hollowed-out hemispheres [256].

Extrusion of pastes containing catalyst powder, binders and lubricants is a frequently used industrial shaping method [250], [256], [263]. Depending on the properties of the paste, press or screw extruders are applied. Press extruders are principally suitable for viscous pastes. Screw extruders are preferred for thixotropic masses. In both cases, pastes are forced through a die, and the extruded material is cut with a special device to a desired length and falls onto a moving belt that transports it through a drier or calciner [250], [256], [263]. Poly(vinyl alcohol), powdered stearine, and Al stearate are used as lubricants. If the mass being extruded contains alumina, then peptizing agents such as nitric acid are added mainly to improve the mechanical strength [250], [255], [256].

Another type of binder is calcium aluminate cement, which sets up by treatment with steam [250], [256].

The extruded material can have different shapes, such as cylinders (noodles), hollow cylinders (macaroni), or ribbed cylinders. The sizes depend on the shape and are in the range of 1.5 – 15 mm diameter [256], [265].

Added organic lubricants and pore-forming agents can be removed by calcination in a stream of air.

Special extrusion techniques and equipment are necessary to produce honeycombs.

Extruding is less expensive than pelletizing, but extrudates have less resistance to abrasion than pellets. Extrudates are suitable for different types of *fixed-bed reactors* operating in the gas or trickle phase.

Pelletizing is a very common method for catalyst forming. It is based on compression of a certain volume of powder in a die between two moving punchers, one of which also serves to eject the formed pellet [250], [256], [263]. Depending on the size and the shape of the prepared pellets, the material being pelletized must be crushed and forced through a correspond-

ing sieve [256]. Furthermore, lubricants such as graphite, Al stearate, pol(vinyl alcohol), kaolin, and bentonite are added before the material enters the tabletting machine. The fluidity of the material is required to assure homogeneous filling of the die [250], [256], [263]. As in the case of extrudates, organic lubricants can be removed by calcination of the pellets.

Industrial pelleting machines are equipped with around thirty dies and produce about 10 liter of pellets per hour or more, depending on their shape and size. Pressures in the range 10 – 100 MPa in the pelleting machine are common [250], [256], [263].

Commercially, cylindrical pellets with sizes such as 3×3, 4.5×4.5, 5×5, or 6×6 mm are offered [250], [256], [263]. Production of 3×3 mm pellets is more expensive than that of larger sizes. Besides cylindrical pellets, various companies provide rings, cog wheels, spoked wheels, multi-hole pellets, etc. [264], [265].

Pellets of different shapes and sizes are suitable for various types of fixed-bed reactors.

5. Characterization of Solid Catalysts

Catalytic activity and selectivity critically depend on the morphology and texture, surface chemical composition, phase composition, and structure of solid catalysts. Therefore, many physical and chemical methods are used in catalysis research to characterize solid catalysts and to search for correlations between structure and performance of catalysts. These methods include classical procedures [266] as well as techniques developed more recently for the study of the chemistry and physics of surfaces [266].

5.1. Physical Properties

5.1.1. Surface Area and Porosity [267], [268]

The specific surface area of a catalyst or support (in m^2/g) is determined by measuring the volume of gas, usually N_2, needed to provide a monomolecular layer according to the Brunauer – Emmett – Teller (BET) method.

In this approach, the determination of the monolayer capacity is based on the physisorption of the test gas. The volume adsorbed at a given equilibrium pressure can be measured by static methods, namely, volumetric or gravimetric measurements. Flow or dynamic techniques are also applied.

The *total surface area* of a porous material is given by the sum of the *internal* and *external* surface areas. Pores are classified as *micropores* (pore width < 2 nm), *mesopores* (pore width 2 – 50 nm), and *macropores* (pore width > 50 nm) according to IUPAC definitions [269].

The *specific pore volume*, *pore widths*, and *pore-size distributions* for micro- and mesopores are determined by gas adsorption. For mesopores, the method is based on the dependence of the pressure of capillary condensation on the radius of a pore in which condensation takes place, which is given by the Kelvin equation:

$$\ln (p/p_o) = \frac{V}{RT} \left(\frac{2\sigma \cos\theta}{r_\kappa} \right) \tag{13}$$

where p/p_o = pressure/saturation pressure, V is the molar volume, σ the surface tension of the liquid adsorbate, Θ the contact angle between adsorbate and adsorption layer on pore walls (hence, $\Theta = 0$ is a good approximation), and r_K is Kelvin radius of a pore assuming cylindrical shape. Since an adsorption layer is typically formed before capillary condensation occurs, the geometric radius r_p of a pore is given by the sum of the Kelvin radius r_K and the thickness of the adsorption layer t: $r_p = r_K + t$. *Mesopore size distributions* can be calculated when adsorption and desorption isotherms are available in the full pressure range up to $p/p_o = 0.95$. The mesopore volume V_p is assumed to be completely filled at this relative pressure, which corresponds to $r_p \approx 20$ nm.

In the *micropore* range (pore width < 2 nm), where the pore dimensions are comparable to molecular dimensions, *pore filling* occurs rather than condensation [268]. The Dubinin – Radushkevich and the Dubinin – Stoeckli theories then permit the estimation of pore dimensions from physisorption data. In addition, several empirical methods exist, such as the t-method [270] and the α_s-method [271]. In the original t-method the amount of nitrogen adsorbed at 77 K was plotted against t, the corresponding multilayer thickness

calculated from an universal N_2 isotherm, while in the α_s-method the multilayer thickness t is replaced by the reduced adsorption α_s. Here, α_s is defined as the dimensionless adsorption n^a/n_x^a such that $\alpha_s = 1$ at $p/p_o = 0.4$, and n^a is the adsorbed amount in moles of the adsorbate (e.g., N_2) at a given relative pressure and n_x^a is the amount adsorbed (in moles) at a relative pressure of 0.4.

For meso- and macroporous materials (pore width > 2 nm), the pore size distribution is determined by measuring the volume of mercury (or another nonwetting liquid) forced into the pores under pressure [250]. The measurement, carried out with a *mercury pressure porosimeter*, depends on the following relation:

$$P = \frac{2\pi\sigma\cos\alpha}{r_p} \tag{14}$$

where P is pressure, σ is surface tension of mercury, and α is the contact angle of mercury with solid. At pressures of 0.1 – 200 MPa, pore size distributions in the range of 3.75 – 7500 nm can be measured. Because the actual shape of the pores is not exactly cylindrical as assumed in the derivation of the above equation, the calculated pore sizes and distributions can deviate appreciably from the actual values shown by electron microscopy.

For pore systems with narrow pore size distributions, the *average pore radius* can be approximated by using

$$r_p = 2\, V_p/S_p \tag{15}$$

where V_p is pore volume, and S_p is the surface area. The pore volume of a catalyst or support is given by

$$V_p = 1/\varrho_p - 1/\varrho \tag{16}$$

where ϱ_p and ϱ are the *particle* and *true densities*, respectively. The former is determined by a pycnometer using a nonpenetrating liquid, such as mercury, whereas the true density is obtained by measuring the volume of the solid part of a weighed sample by helium displacement.

In certain instances, pore dimensions can be determined by high-resolution electron microscopy (HREM) [272].

5.1.2. Particle Size and Dispersion [273]

The surface area of active metals dispersed on a support deserves particular consideration since the metal surface area and particle size (which are interrelated quantities) determine the catalytic properties of supported metal catalysts. The metal *dispersion D* is given by $D = N_S/N_T$, where N_S is the number of metal atoms exposed at the surface and N_T is the total number of metal atoms in a given amount of catalyst. The fraction of surface atoms D can be determined if N_S is experimentally available. It can be determined by chemisorption measurements with adsorptives that strongly bind to the metal but which interact negligibly with the support at the chosen temperatures and pressures. H_2, CO, NO, and N_2O have been used for this purpose at or above room temperature [273], and static, dynamic, and desorption methods have been applied. Saturation values of the chemisorbed amounts permit N_S to be calculated if the chemisorption stoichiometries are known.

Dispersion is directly related to particle size and particle size distribution. Assuming reasonable model shapes for the metal particles, average particle sizes can be calculated from the chemisorption data.

Average crystallite size distributions can be determined independently from X-ray diffraction line broadening [273–275], and small-angle X-ray scattering (SAXS) permits the determination of particle sizes and particle size distributions, but also of the specific surface area of the metal and of the support [273–275].

Electron microscopy offers the unique opportunity to observe catalyst morphologies over the entire range of relevant particle sizes [272], [273], [276–278]. Particle shapes and sizes of the support or active phase and their size distributions can be extracted from micrographs, but structural information can be also obtained by electron-diffraction and lattice-imaging techniques [272].

5.1.3. Structure and Morphology

X-ray powder diffraction (see also → Structure Analysis by Diffraction, Chap. 2.6.) (XRD) is a routine technique for the identification of phases present in a catalyst [274], [279]. It is based on the comparison of the observed set

of reflections of the catalyst sample with those of pure reference phases, or with a database (Powder Diffraction File (PDF) distributed by ICDD, the International Centre for Diffraction Data). XRD studies can now be carried out in situ on the working catalyst [279], and the use of synchrotron radiation permits dynamic experiments in real time [280]. Time-resolved studies on a timescale of seconds are now becoming possible. Quantification of phase compositions can also be performed.

More sophisticated analysis of the diffraction patterns of crystalline materials provides detailed information on their atomic structure. The Rietveld method is used for structure refinements. Perhaps more importantly for catalytic materials, the local atomic arrangement of amorphous catalysts is based on the Debye equation, which gives the intensity scattered by a collection of randomly distributed atoms. The Fourier transform of the Debye equation gives the radial distribution function (RDF) of electrons, from which the number of atoms (electrons) located in the volume between two spheres of radius r and $r + \mathrm{d}r$ around a central atom, i.e., the radial density of atoms, can be obtained [279]. This approach has been applied for the structural analysis of amorphous or poorly crystalline catalyst materials and of small metal particles.

X-ray Absorption Spectroscopy (XAS) [281–283], is the method of choice where the applicability of XRD for structure analyses ceases to be possible. Because of their high photon flux, synchrotron facilities are the preferred sources for XAS experiments. The physical principle of XAS is the ejection of a photoelectron from a core level of an atom by absorption of an X-ray photon. The position of the absorption edge gives the binding energy of the electron in the particular core level and is thus characteristic of the respective element and its chemical state (see also → Surface and Thin-Film Analysis, Chap. 2.1.) and the shape of the absorption edge provides information on the distribution of the local density of states (LDOS).

The ejected photoelectron wave is backscattered at neighboring atoms, and the scattered wave interferes with the outgoing primary wave. This interference results in a modulation of the absorption coefficient at energies between 50 and 1000 eV beyond the absorption edge (extended X-ray absorption fine structure, EXFAS). Analysis of these oscillations provides information on the chemical nature of atoms at well-defined distances from the central (ionized) atom and gives coordination numbers. Qualitative information on coordination of the central atom may also be obtained from the observation of pre-edge peaks. Information on dynamic and static disorder can also be extracted from the EXAFS. Hence, a detailed microscopic picture of the structure of a catalyst can be derived. XAS is particularly attractive for studies of catalysts under working conditions, although there are limitations regarding temperature [281]. The combined application of XAS and XRD on the same sample using synchrotron radiation for in situ studies is an ideal tool in catalysis research [284].

Electron Microscopy and Diffraction [272], [276–278], (see also → Microscopy, Chap. 2.). When electrons penetrate through matter in an electron microscope, contrast is formed by differential absorption (amplitude contrast) or by diffraction phenomena (phase contrast). Electron micrographs of catalyst materials can provide for identification of phases, images of surfaces and their morphologies, and elemental compositions and distributions. Image interpretations are often not straightforward and need expert analysis. Several variants of electron microscopy use different electron optics and working principles and therefore have to be chosen according to the problem to be solved.

Conventional transmission electron microscopy (CTEM) operates in the 100 – 200 kV range of electron energies, and imaging is based on amplitude contrast in the bright-field mode. Point resolutions of 0.2 – 0.3 nm can be achieved in favorable cases. A typical application of CTEM in catalysis research is the examination of metal particle sizes and their distributions in supported catalysts.

Dark-field images are produced when the directly transmitted electron beam is excluded by the objective aperture, and only diffracted electrons are used for imaging. This mode of operation selectively detects crystallites with crystallographic spacings within a narrow range.

High-resolution electron microscopy (HREM) can be performed in CTEM instruments by modifying the mode of imaging, or

in dedicated instruments operating at electron energies of 0.5 – 1.0 MeV. HREM images can be directly related to the atomic structure of the material [285]. Lattice fringes can be resolved, and the determination of the spacings of atomic planes is enabled. Support particles can thus be identified, and the crystal structure of heavy metal particles having sizes in the range down to 1 nm can be investigated.

In dedicated *scanning transmission electron microscopes* (STEM) an annular detector provides the image formed from diffracted beams, while the central transmitted beam can be further analyzed by using an electron spectrometer to simultaneously provide elemental analysis. The intensity distribution of electrons scattered at high angles (40 – 150 mrad) depends on the square of the atomic number Z according to the Rutherford scattering cross section. The STEM images are therefore also called Z-contrast images, and they are particularly useful for the study of catalysts containing small metal particles [272].

In *scanning electron microscopy* (SEM) the image is produced by scanning a finely focused probe beam in a raster pattern across the specimen surface. Emitted signals such as backscattered and secondary electrons are detected and used for image formation. Secondary electrons are most commonly used. The best resolutions that can be achieved with current generation SEM instruments are approximately 1 nm. SEM is most useful for studying sample topographies, and it can be applied with a significant background pressure of a reactive gas while the sample is observed (environmental SEM or ESEM).

Selected area electron diffraction (SAED) provides information on phase compositions and structures at a microscopic level. The combination of microdiffraction patterns and bright-field images enables the determination of shapes and exposed facets in dispersed phases in solid catalysts.

Analytical electron microscopy (AEM) permits the determination of the elemental composition of a solid catalyst at the microscopic level by energy dispersive detection of the electron-induced X-ray emission. Energy dispersive spectroscopy (EDS) is sensitive for elements with atomic numbers $Z > 11$. For lighter elements ($Z < 11$), electron energy loss spectroscopy EELS is applied.

Controlled atmosphere electron microscopy (CAEM) [272], [286] is arousing considerable interest as it will permit the observation of changes in the catalyst structure and morphology under reaction conditions.

Vibrational Spectroscopy [287] (→ Infrared and Raman Spectroscopy). Vibrational spectroscopy is one of the most promising and most widely used methods for catalyst characterization, since it provides detailed structural information on the solid catalyst material and on surface groups and adsorbates. Several vibrational spectroscopic methods can be applied in situ, and they can be successfully used for studies on ill-defined high surface area porous materials. In situations where X-ray diffraction techniques are not applicable, vibrational spectroscopy can often provide information on phase transitions and changes in compositions of bulk catalyst materials, on their crystallinity, and on the nature of surface functional groups. Most vibrational spectroscopic methods are not surface-sensitive, but they become surface-sensitive when vibrational spectra are recorded for groups or adsorbates that are present exclusively at the material's surface. Representative examples for the structural characterization of solid catalysts by vibrational spectroscopy are bulk oxides (including simple binary oxides, multicomponent materials such as oxidation catalysts, and zeolites and molecular sieves), and supported oxides (e.g., monolayer-type catalysts), and sulfides. The vibrational analysis of surface groups, particularly of hydroxyl groups, can also be addressed. In many cases surface hydroxyl groups (e.g., on oxides) are simply formed by dissociative chemisorption of water molecules, which reduces the surface free energy. Hydroxyl groups can also be constituents of the solid-state structure, for example as in zeolites.

There are several methods and techniques of vibrational spectroscopy which are particularly suitable in catalysis research. *Infrared transmission – absorption spectroscopy* is the most commonly used technique. The KBr disk technique is routine for transmission spectroscopy of powder samples. However, for in situ investigations pressed self-supporting wafers have to be used. Samples which exhibit only weak bulk absorption, and the av-

erage particle size d of which is smaller than the wavelength of the infrared radiation ($d < \lambda$) are optimally suited for the transmission mode. Transmission – absorption infrared spectroscopy has been particularly successful in elucidating the structure of hydroxyl groups [119], [287]. More strongly absorbing materials, and particularly those having average particle sizes greater than the wavelength of the infrared radiation, which therefore cause significant scattering losses in transmission, may preferentially be studied by *diffuse reflectance spectroscopy* (DRS, DRIFT). A powerful technique for structural studies on catalytic materials under extreme temperature and pressure conditions is *laser Raman spectroscopy* (LRS), although laser heating and laser-induced fluorescence may cause serious problems. One way, among others [287], to avoid fluorescence is to use of UV light instead of visible radiation for spectral excitation [288]. LRS has been successfully applied for the structural characterization of complex oxides, zeolites, and supported oxides and sulfides [287]. *Surface-enhanced Raman spectroscopy* (SERS) has found some application in studies of finely divided metal catalysts, particularly silver [289]. *Second harmonic generation* (SHG) and *sum frequency generation* (SFG) [290], [291] are nonlinear optical techniques with high surface sensitivity which will probably find increasing application in studies relevant to catalysis.

Neutron techniques [292] include *neutron diffraction* and *inelastic neutron scattering* (INS). Both techniques are particularly sensitive to light elements (such as H or D) and provide complimentary structural information to XRD.

5.1.4. Local Environment of Elements

Nuclear spectroscopic methods provide information on the local environment of several selected elements.

Mössbauer spectroscopy and time differential perturbed angular correlation (TDPAC) belong to the class of techniques which detect solid-state properties mediated by hyperfine interactions via nuclear spectroscopy [293]. Both techniques are γ spectroscopies; they are bulk techniques and can be applied under in situ conditions, although Mössbauer spectroscopy requires low temperatures.

Mössbauer spectroscopy (Mössbauer Spectroscopy) [293], [294] provides information on oxidation states, phases, lattice symmetry, and lattice vibrations. Its application is limited to elements which exhibit the Mössbauer effect, such as iron, cobalt, tin, iridium, ruthenium, antimony, and platinum. Particularly valuable information on catalyst structures has been obtained for iron catalysts for Fischer-Tropsch and ammonia synthesis, and for cobalt-molybdenum hydrodesulfurization catalysts.

The time differential observation of the perturbed angular correlation of γ rays emitted from radioactive nuclei (TDPAC) [293], [295], [296] is a γ-spectroscopic technique which also allows the determination of hyperfine interactions such as nuclear electric quadrupole interactions (NQI). The NQI parameters enable local structural information around the γ emitter to be extracted. The technique has been successfully applied in studies on molybdenum-containing catalysts, and its application to tungsten seems promising.

Solid State Nuclear Magnetic Resonance [297–299] (see also → Nuclear Magnetic Resonance and Electron Spin Resonance Spectroscopy, Chap. 4.). NMR spectroscopy in heterogeneous catalysis principally allows the characterization of the chemical and structural environment of atoms in the catalysts (or in species adsorbed on catalyst surfaces). NMR studies on catalysts can be carried out over a wide range of temperatures and pressures, as well as in the presence of gases and liquids. Information can therefore be derived about the structures of catalysts and their thermal or chemical transformations. In addition, specific adsorbent – adsorbate interactions, the nature of chemically bonded surface species, and chemical reactions occurring at the catalyst surface can be studied. Most elements of interest in catalysis have isotopes that can be studied with modern NMR spectrometers. Isotope enrichments may be desirable or even necessary for certain elements, for example, ^{17}O.

NMR spectra of solids are often complex since structure-dependent interactions such as dipolar interactions, chemical shift interactions,

quadrupolar interactions (for nuclei with spin $I > 1/2$) contribute strongly to the shape and position of NMR lines. Because of their structure-dependence these interactions are the main source of information on the structural environment of the nucleus in question. The selective determination of the related interaction parameters of structurally unequivalent nuclei is the major goal of an NMR experiment. In well-crystallized samples, the interaction parameters adopt unique values, while in poorly crystallized or amorphous powders they must be described by distribution functions.

The anisotropy of the above-mentioned interactions results in line broadening, and the spectra of polycrystalline samples consist of a broad superposition of signals arising from different orientations of the crystallites relative to the direction of the external magnetic field B_o, weighted by the statistical probability with which each orientation occurs (powder patterns). Special techniques have been developed which remove or at least reduce substantially these line-broadening effects and permit highly resolved NMR spectra of powders with individual lines for inequivalent nuclei to be recorded. The most important of these techniques are *dipolar decoupling*, *magic-angle spinning* (MAS), and *double oriented rotation* (DOR). *Cross-polarization* (CP) improves the sensitivity for nuclei with low natural abundance and allows the spatial proximity of nuclei to be monitored.

Typical examples for structural characterizations by solid-state NMR [297] are studies on zeolites using ^{27}Al and ^{29}Si NMR. Information on the distribution of Al in the environment of Si atoms and on the possible presence of nonframework Al species has been obtained. The location of exchangeable alkali metal ions has been studied by ^{23}Na and ^{133}Cs NMR. Vanadium- and molybdenum-based catalysts have successfully been characterized by ^{51}V and ^{95}Mo NMR.

5.2. Chemical Properties

5.2.1. Surface Chemical Composition

The atomic composition of a catalyst surface plays a decisive role for the catalytic properties. Electron and ion spectroscopies [300] are surface-sensitive analytical tools which provide information on the atomic composition within the topmost atomic layers. The information depth, i.e., the number of atomic layers contributing to the measured signal, depends on the method. Concentration profiles can be obtained by sputter etching of the surface by ion bombardment. The application of these particle spectroscopies requires ultrahigh-vacuum (UHV) conditions.

The basis for the identification of atoms on surfaces of solid materials by electron spectroscopies, such as *Auger electron spectroscopy* (AES) and *X-ray photoelectron spectroscopy* (XPS) are the electronic binding energies. With ion spectroscopies, such as *low-energy ion scattering* (LEIS) and *Rutherford backscattering*(RDS), surface atoms are identified by their nuclear masses. Ion bombardment of surfaces is accompanied by sputtering processes (surface etching) which lead to the removal of secondary ionic and neutral particles. These are analysed by mass spectroscopic techniques, such as *secondary ion mass spectroscopy* (SIMS), and *secondary neutral mass spectroscopy* (SNMS). Less frequently used is *laser microprobe mass analysis* (LAMMA). Relevant information on the properties of the various surface analytical techniques is summarised in Table 10.

The physical principles of the various techniques have been discussed in several articles and monographs [300], [301].

Electron Spectroscopy (AES, XPS) (see also → Surface and Thin-film Analysis, Chap. 2.3.). These techniques use electrons as information carriers. The electrons can be produced by the absorption of photons resulting in photoemission. In XPS, X-ray photons are used to ionize core levels, and the kinetic energy E_k of the emitted photoelectrons is measured. The energy balance is given by:

$$E_k = h\nu - E_b - \Phi \quad (17)$$

This equation permits the electron binding energy E_b (relative to the Fermi level) to be measured when the photon energy $h\nu$ and the work function Φ of the spectrometer are known. The binding energies are characteristic for a particular element.

As a result of the photoionization a singly ionized atom is formed, which can also be produced

Table 10. Characteristics of surface analytical techniques in standard applications (adapted from ref. [300])

Information	Technique					
	AES	XPS	LEIS	RBS	SIMS	SNMS
Surface sensitivity (monolayers)	2–5	5–10	1–2	20–50	2–4	2–4
Detection limits (monolayers)	$10^{-2}-10^{-3}$	10^{-2}	10^{-3}	10^{-3}	10^{-6}	10^{-6}
Quantification ∗	+	++	+	+++	–	+
Chemical information ∗	(+)	+	–	–	+	–
Structural information ∗	–	(+)	(+)	+	(+)	–

∗ Increasing number of positive signs indicates better capabilities; parentheses indication of restriction to special conditions.

by electron impact. The core hole (e.g., in the K shell) can be filled by an electron from a higher shell (e.g., the L_1 shell) and the energy of this de-excitation process can be released by emission of an X-ray photon (*X-ray fluorescence*, XRF) or can be transferred to another electron (e.g., in the L_2 shell) which is then emitted with a well-defined kinetic energy (Auger process). This kinetic energy is determined by the orbital energies E_K, E_{L_1}, and E_{L_2} of the three orbitals involved. The Auger energy E_{KLL} is then given by:

$$E_{KLL} = E_K - E_{L_1} - E_{L_3} - \delta E - \Phi \quad (18)$$

where δE is a relaxation energy, and Φ the spectrometer work function. Clearly, E_{KLL} is characteristic for an element and independent of the initial ionization process. Thus, both techniques permit the elemental constituents of a surface to be identified.

The information depth of both electron spectroscopies is determined by the mean free path of the emitted electrons, which depends on the kinetic energy of the electron in the solid matrix. This dependence is known [300–302]. The electron mean free path is typically larger in oxides than in metals at equal energy, and it is particularly large for zeolites because of their low density. Together with reported ionization cross sections and, in the case of AES, Auger decay probabilities, quantitative surface analysis is possible. The ratios of integral peak areas are proportional to concentration ratios. These can be analyzed as a function of preparation and treatment conditions of a given catalyst system (e.g., supported metal, oxide, or sulfide catalysts) and compared with model calculations [301]. Information on the elemental distributions and on dispersions of active components thus becomes available.

Ion-scattering Spectroscopies [300] (see also → Surface and Thin-Film Analysis, Chap. 3.3.). In ion-scattering spectroscopies solid surfaces are bombarded with monoenergetic ions, which are scattered on the top atomic layer (ion energies of about 0.5 – 5 keV, *low-energy ion scattering* (LEIS) [303], [304]) or within near-surface regions (ion energies of about 0.1 – 23 MeV, *Rutherford backscattering* (RBS) [305], [306]). In both cases the collision kinematics can be described as simple binary collisions, so that the kinetic energy of the backscattered ion is directly dependent on the ratio of the masses of the projectile and the scattering target atom and on the scattering angle. The mass of the projectile is known and the scattering angle is fixed and determined by the geometry of the spectrometer. Thus, the mass, and hence the identity, of the scattering target atoms can be determined unequivocally.

The LEIS technique provides information on the nature of the atomic constituents of the topmost atomic layers. Quantitative analysis, however, is difficult since neutralization probability, which makes the technique surface sensitive, is not easily available. Only a few percent of the primary ions are backscattered as ions in the case of noble gas ion (e.g., He^+). The technique can be applied for the characterization of real catalyst surfaces, although surface roughness reduces the signal intensity.

In contrast, in the energy regime of RBS the scattering cross sections can be calculated exactly. As a consequence, quantitative analysis is possible by RBS, but the surface sensitivity is lower than for LEIS. In optimal cases an information depth of 1 – 5 nm can be achieved. A combined application of LEIS, RBS, and perhaps XPS is often most informative [300].

Secondary Particles. Ion bombardment of a surface leads to ion etching with the release of atoms and molecular fragments with varying charges (anions, cations, and neutrals) and excitation states. The mass analysis of secondary ions by mass spectrometry [*secondary ion mass spectroscopy* (SIMS)] has been developed as a highly sensitive and powerful surface analytical method (→ Surface and Thin-Film Analysis, Chap. 3.1.) [307], [308]. Although destructive because of the need for sputtering, the sputtering rate can be kept low in the so-called static mode (low primary-ion current density) so that the surface remains essentially unchanged. Since the sputtered particles are preferentially released from the first two atomic layers, the SIMS technique is surface-sensitive. In contrast to the ion-scattering techniques, not only atomic constituents of a surface can be detected but information on the local environment of an atom in the surface can be obtained by analysis of molecular fragments. The detection of light elements, particularly hydrogen, is also possible. Quantification of the method is difficult, although not entirely impossible.

A high percentage of the sputtered secondary particles are neutral and must be postionized for mass spectroscopic analysis [*secondary neutral mass spectroscopy* (SNMS), → Surface and Thin-Film Analysis, Chap. 3.2.] [309], [310]. Post-ionization can be achieved by electron impact in a plasma or by an electron beam. Alternatively, resonant and nonresonant laser ionization can be applied. Applications of SNMS for catalyst characterization have still not been reported.

5.2.2. Valence States and Redox Properties

Electron Spectroscopies. *X-ray photoelectron spectroscopy* (XPS) and *Auger electron spectroscopy* (AES), in addition to elemental analysis, permit information to be obtained on the valence and bonding states of a given element. This is due to the fact that the core-level binding energies and Auger kinetic energies are dependent on the chemical state, which leads to characteristic chemical shifts. In solids, the Madelung potential also plays an important role [301], [311], [312]. In addition, the ionization of an atom leads to relaxation phenomena which provide a relaxation energy that is carried on by the emitted photoelectron. The binding energy of a core electron in level C of an atom is given by:

$$E_{\mathrm{b}}\,(\mathrm{C}) = \mathrm{const.} + \sum_j (q_j/R_j) + kq - R_{\mathrm{ea}} \qquad (19)$$

where q_j are the charges of all other atoms and R_j their distances from the core-ionized atom. The constant is the Hartree-Fock energy of the core electron in the atomic level C for the free atom, k is the change of the core potential resulting from the removal of an electron, and R_{ea} represents the extra-atomic polarization energy.

For an Auger transition involving the atomic levels C, C′, and C″, the kinetic energy E_{k}(C, C′, C″) of the Auger electron is related to the photoelectron binding energy E_{b}(C) in good approximation by:

$$\alpha' = E_{\mathrm{b}}\,(\mathrm{C}) + E_{\mathrm{k}}\,(\mathrm{C,C',C''}) = \mathrm{const.} + R_{\mathrm{ea}} \qquad (20)$$

where α' is the so-called Auger parameter.

Chemical shifts and the Auger parameter provide detailed information on the chemical state of an element as regards its oxidation state and its local environment. The latter is reflected in the Auger parameter, which is dependent on the extra-atomic polarization energy and hence, on the structural and bonding characteristics of the atom under consideration. So-called Wagner plots [312], [313] in which the XP binding energy, the Auger energy, and the Auger parameter are correlated for families of compounds often permit the analysis of a compound of unknown structural and bonding characteristics.

Optical Spectroscopy and Electron Paramagnetic Resonance. Optical excitations in the UV, VIS, and NIR regions and electron paramagnetic resonance (EPR) are classical techniques which provide information on the electron configuration (oxidation state) of a metal center and on the symmetry of the ligand sphere [314–317]. While optical spectroscopy is applicable to practically all systems, EPR is limited to paramagnetic species, i.e. those which contain one or more unpaired electrons.

UV–VIS–NIR spectroscopy covers a wide range of energies (typically 0.5 – 6 eV or 4000 to 50 000 cm^{-1} or wavelengths (2500 to 200 nm) as shown in Figure 16. Several types of transitions occur in this range, namely, chargetransfer

(CT) and $d-d$ transitions, as also indicated in Figure 16. The first class of excitations involves two adjacent atoms, one of which is typically a metal center and the other a ligand or another metal atom. Electromagnetic radiation can promote charge transfer from the ligand (L) to the metal (M), from the metal (M) to the ligand (L) or from one metal center to another. These transitions are therefore called ligand-to-metal CT (LMCT), metal-to-ligand CT (MLCT), and metal-to-metal CT (MMCT), respectively. Such transitions occur in molecular complexes and in nonmolecular solids, such as metal oxides. The energy of CT transitions depends on the symmetry and oxidation state of the metal center and on the nature of the ligand or of the second metal atom [318]. Hence, information on these properties can be extracted from CT spectra. These spectra are relatively intense since they are dipole-allowed. In contrast, metal-centered or intra-atomic transitions in transition metal atoms or ions (ligand-field or $d-d$ transitions) are of moderate or weak intensity because they are forbidden by the Laporte (orbital) selection rule (and also by the spin selection rule) unless the selection rules are relaxed by vibronic or spin–orbit coupling. The $d-d$ transitions also provide information on the electron configuration and on the symmetry of a complex (or local environment in a solid). Typical systems that have been studied by optical spectroscopy are transition metal and base metal oxides, transition metal ions or complexes grafted on support surfaces, and transition metal ion-exchanged zeolites.

While spectra of liquid samples can be recorded in the transmission mode, catalyst powders must be studied by the diffuse reflectance technique (DRS) [315], [316], [319]. The measured diffuse reflectance can be converted into the so-called Schuster–Kubelka–Munk (SKM) function, which is directly proportional to the absorption coefficient. The wavelength dependence of the SKM function is thus equivalent to an absorption spectrum, provided the scattering coefficient is independent of the wavelength. This condition is often fulfilled in the UV and VIS spectral regions. Simple quartz cells for in situ treatments can be designed, to which an EPR tube can also be connected for simultaneous optical spectroscopy and EPR on the same sample [314].

Figure 16. Energy ranges of different types of electronic transitions (adopted from [314])

Luminescence spectroscopy [320], [321] has proved to be a valuable addition to the spectroscopy techniques for characterization of solid catalysts under well-defined conditions.

As mentioned above, *electron paramagnetic resonance* (EPR) is used to study paramagnetic species in catalytic materials. Besides the simple qualitative (and quantitative) detection of the presence of paramagnetic sites, the spin density distribution at the paramagnetic center and on the neighboring atoms can be deduced from the spectra. Simulations of EPR spectra are often useful for full interpretation. The extremely high sensitivity of the EPR technique can be an advantage but also a drawback because the importance of minority radical species may be overemphasized. EPR is not surface-sensitive. However, radical species in the surface can easily be identified by exposing the sample to paramagnetic O_2, which leads to significant broadening or disappearance of signals of surface species because of dipole–dipole interactions.

Several reviews on the use of EPR in catalyst characterisation have been published [314], [322], [323]. Typical applications of EPR are the detection of paramagnetic states of transition metal ions and analysis of the symmetry of their ligand sphere and/or their coordination, redox properties of catalytic materials and their surfaces, and surface anion or cation radicals deliberately produced by organic molecules as probes for the redox properties of the solid catalyst. Radical species (e.g., in connection with

coke formation) formed during catalytic reactions have also been detected.

Thermal Analysis. Thermoanalytical techniques such as *differential thermal analysis* (DTA), *thermogravimetry* (TG), and *differential scanning calorimetry* (DSC) are well-established methods (→ Thermal Analysis and Calorimetry) in solid-state chemistry [324], [325] which have successfully been applied to investigating the genesis of solid catalytic materials. They can also be used to follow reduction and oxidation processes by measuring either thermal effects and/or weight changes. When combined with an on-line mass spectrometer, changes in the gas-phase composition occurring during chemical transformations of the solid sample can be monitored simultaneously.

In temperature-programmed reduction (TPR), as first described by Robertson et al. [326], a stream of inert gas (N_2 or Ar) containing ca. 5 vol % H_2 is passed through the catalyst bed of a flow reactor containing a reducible solid catalyst [327]. By monitoring continuously the H_2 concentration in the gas stream and its eventual consumption with a thermal conductivity detector while heating the sample with a linear temperature ramp of ca. 10 K/min, the rates of reduction are obtained as a function of time (or temperature). The total amount of H_2 consumed determines the reduction equivalents present in the catalyst, and detailed analysis of the experiment permits the kinetic parameters of the reduction process to be determined and provides information on reduction mechanisms. Characteristic numbers which depend on the experimental parameters (amount of reducible species present, H_2 concentration, flow rate, and temperature ramp) have been defined [328], [329]. These numbers must be kept in certain ranges for optimal performance of the experiment.

TPR experiments have been used to investigate the reduction behavior of bulk and supported reducible species, solid solutions, promoted metal catalysts, metals in zeolites, and of supported sulfides and of nitrides [327].

Temperature-programmed oxidation (TPO) is an equally valuable technique for investigating the oxidation kinetics and mechanisms of reduced materials [327]. Cyclic application of TPR and TPO provides information on the redox behavior of catalytic materials, e.g., of catalysts for selective catalytic oxidations.

5.2.3. Acidity and Basicity

Acid-catalyzed reactions are among the industrially most important hydrocarbon conversions. Acid sites can be classified as Lewis acidic sites, such as coordinatively unsaturated cations (e.g., Al^{3+} on the surface of partially dehydroxylated alumina, and Brønsted acidic sites, which are typically surface OH groups as, e.g., in H forms of zeolites. Carbenium and carbonium ions are thought to be formed by protonation of hydrocarbons on these groups. Surface oxygen ions may function as Lewis basic centers, and if strong enough they may abstract protons from hydrocarbon molecules to form carbanion intermediates. A typical solid base is MgO.

For characterisation of acid and base properties, the nature (Lewis or Brønsted) of the sites, the acid or base strength, and the number of sites per unit surface area of a solid catalyst must be determined. Brønsted acidity is almost certainly required for all acid-catalysed reactions. However, the mechanistic details on surfaces are significantly different from the well-known carbenium and carbonium ion chemistry in solution, because of the lack of the stabilizing effect of solvation in heterogeneously catalysed gas-phase reactions. As shown by Kazansky [330], the electronic ground state of surface acidic OH groups of oxides and in H forms of zeolites is essentially covalent. The main differences in their acid strength are thought to be due to the energetic positions of their electronically excited heterolytic terms. Similarly, the interaction of acid groups with alkenes does not result in the formation of adsorbed carbenium ions but rather in the formation of more stable covalent alkoxides. Basic sites (surface O^{2-} ions) in the vicinity of OH groups could be involved in this process. Carbenium ions (and even more so carbonium ions) are therefore not considered to be reaction intermediates in solid acid catalysis, but rather excited unstable ion pairs or transition states resulting from electronic excitation of covalent surface alkoxy species. Because of the proposed bifunctional nature of active acid sites in heterogeneous acid catalysis, it is necessary to characterise both the acidic and basic properties of solid catalysts.

Many different methods have been developed for the characterisation of acidity, but only little is known about the basic character, particularly of materials that are typically considered to be acid catalysts.

Chemical Characterisation [331]. Titration methods in aqueous medium are not very informative, because H_2O tends to strongly modify surface properties by molecular or dissociative chemisorption. Therefore, nonaqueous methods have been proposed, in which the solvent (e.g., benzene or isooctane) does not or only weakly interact with the catalyst surface. Hammett indicators were used to determine the acid strength in terms of the Hammett – Deyrup H_0 function:

$$H_0 = -\log a_{H^+}(f_B/f_{BH^+}) \quad (21)$$

where a_{H^+} is the proton activity and f_B and f_{BH^+} are the activity coefficients of the basic probe and its protonated form, respectively. A series of Hammett indicators covers the range of $-18 < H_0 < 4$, where $H_0 = -12$ corresponds to 100 % H_2SO_4.

Site densities and acid strength distributions were determined by the *n*-butylamine titration method [332]. As these titration and indicator methods can yield erroneous results [333], they are not frequently used today.

Isosteric heats of adsorption of strong bases (e.g., pyridine) may be considered as measures of acid strength. However, a discrimination between Lewis and Brønsted sites is not possible.

Temperature-programmed desorption [also called *thermal desorption spectroscopy* (TDS)] of basic probe molecules has been developed as a powerful tool for the characterisation of solid acids [334], [335]. In this method, a strong base is isothermally pre-adsorbed on an acidic catalyst and then exposed to a stream of inert gas (e.g., He). Heating by a temperature ramp (ca. 10 K/min) leads to desorption of the base. The integral area of the desorption peak gives the total acid site density, and the position of the peak maximum provides the activation energy of desorption (which may be close or identical to the heat of adsorption), which can be considered to be a measure of the acid strength. This approach has been applied for investigations of H forms of zeolites using ammonia as the probe [336], [337]. However, discrimination between Lewis and Brønsted acid sites is again only possible with the assistance of, e.g., vibrational spectroscopy.

Microcalorimetry [334]. Differential heats of adsorption of probe molecules can be measured with high accuracy by heat-flow calorimetry and differential scanning calorimetry. These data provide information on the acid (or base) strength distribution. Ammonia and other amines have been used as probes for acid sites on oxides [338] and in H forms of zeolites [339], [340], and carbon dioxide and sulfur dioxide were adsorbed as acidic probes on several oxides [338].

Vibrational spectroscopy [341–346]. *Transmission infrared spectroscopy* is the most frequently applied technique for investigations into acidic and basic properties of solid catalysts. Surface hydroxyl groups can easily be detected since they function as dipolar oscillators. However, the stretching frequency of unperturbed OH groups can not be taken as a measure of the acid strength. Lewis acidic and basic centers can only be detected by vibrational frequencies with the adsorption of suitable probe molecules. Criteria for the selection of optimal probe molecules have been defined by Knözinger et al. [341], [346].

The use of basic probe molecules permits a discrimination between Brønsted and Lewis acid sites. When a base B is adsorbed on an acidic OH group, hydrogen bonding followed eventually by protonation of the base may occur (Eq. 20):

$$OH + B \rightleftharpoons OH \cdots B \rightleftharpoons O^- \cdots H^+B \quad (22)$$

The strength of the hydrogen bond and the ability of the OH group to protonate the base is determined by the acid strength of the surface OH group and by the base strength (or proton affinity) of B. When hydrogen bonding occurs, the induced frequency shift of the O – H stretching mode $\Delta\tilde{\nu}_{OH}$ is a measure of the strength of the hydrogen bond ΔH_B (Eq. 23) [347] and hence, of the acidity of the OH group.

$$|\Delta\tilde{\nu}_{OH}|^{1/2} \sim \Delta H_B \quad (23)$$

Simultaneously, internal molecular modes of the base B are modified, particularly when protonation occurs. These changes can also be used

for the interpretation of the bonding type of the probe. Strong bases such as the traditional probe molecules ammonia and pyridine are protonated by even very weak Brønsted sites which may not be at all relevant in acid catalysis. Weaker bases such as nitriles, carbon monoxide, and even dinitrogen and dihydrogen only undergo hydrogen bonding (hydrogen bonding method [342]), but due to their weak interactions they are very specific and can provide very detailed information on the properties of acidic surfaces.

The same bases can be used for the detection of Lewis acid sites L, with which they form surface coordination compounds:

$$L + B \rightleftharpoons L \leftarrow B \tag{24}$$

The frequency shifts of the internal B modes are a measure of the nature and strength of the coordinative bond. For example, carbon monoxide when coordinated to L sites undergoes very typical shifts of the C – O stretching frequency which provide information on the nature of the element and of the coordinative bond, on the oxidation state, and on the coordination of the L site [341], [346].

The investigation of basic sites O^{2-} by acidic probe molecules AH with analysis of the vibrational spectra is much less advanced than that of acid sites. The hydrogen-bond method can in principle be applied:

$$O^{2-} + H\text{–}A \rightleftharpoons O^{2-} \cdots H\text{–}A \tag{25}$$

Here the shift of the H–A stretching mode is a measure of the hydrogen-bond strength and hence, the basic character (proton affinity) of the surface O^{2-} site. Recently, CH compounds such as trichloromethane [342], acetylene and substituted acetylenes [346], [348] and even methane [350] were proposed and successfully tested as acidic probe molecules. Pyrrole [345] and several Lewis acids [341] have also been used.

Surface chemical transformations of, e.g., CO_2, alcohols, ketones, acetonitrile, and pyridine gave detailed information on the bifunctional acid – base pair character of several oxides, particularly of alumina [341], [351].

Nuclear Magnetic Resonance [352–354]. Solid-state ^1H magic-angle spinning (MAS) NMR spectroscopy measures proton chemical shifts, which were thought to reflect the deprotonation energies of surface OH groups. However, proton chemical shifts are also very sensitive to hydrogen bonding. Therefore, changes in proton chemical shifts induced by hydrogen bonding of probe molecules can also be used for the characterization of protonic acidity.

Dissociative chemisorption of CH_3I was proposed for characterization of surface basicity by ^{13}C NMR spectroscopy [356].

5.3. Mechanical Properties [357]

Catalyst particles are exposed to diverse mechanical strains during transportation, charging to the reactor, and operation. In fixed bed reactors catalyst particles must withstand pressure caused by the mass of the catalyst charge and erosion by high-velocity gas streams. In fluidized- and moving-bed reactors, the particles must resist attrition from rubbing against each other and from colliding with the walls of the reactor system. The technical performance of catalysts depends on their mechanical strength to maintain integrity for a reasonable time in spite of these strains.

There are three types of methods for determining the strength of catalysts used under static conditions [358]. For pellets and rings with no areas of distortion (preferably sized 1 cm or larger), the *crushed* (or crush) *strength* is determined by exerting pressure on the specimen placed between two horizontal plates of a hydraulic press. The upper plate moves down until the specimen is crushed, at which point the pressure is recorded. The test is repeated for several particles, and the values are averaged. In the knife edge hardness test, the upper plate of the press is replaced by a knife with a 0.3 mm edge. A mass of 1 kg is applied to the knife and the percentage of broken samples is recorded. The mass is then raised in increments of 1 kg, and the test is repeated until 100 % of the particles are broken or until a mass of 10 kg is reached. Catalyst particles of irregular form are tested in a cylinder provided with a ram. After a definite pressure is applied, the sample is discharged, and the weight percent of fines formed during the test is determined by screening.

Tests for impact strength and resistance against abrasion or attrition are carried out un-

der dynamic conditions. For *impact testing* of very strong catalysts (e.g., ammonia synthesis catalysts), a mass of 500 – 1000 g is dropped on the particle from a standard height and the percentage of unbroken, split, and broken samples out of 20 or more is recorded. *Abrasion tests* on tableted and extruded catalysts are carried out in a rotating horizontal steel cylinder provided with one baffle. The percent of fines (based on the mass of the catalyst tested) formed after 1 h is reported as attrition loss. The *attrition loss* of fluid catalysts is measured by exposing the catalyst particles to a high-velocity air stream in a glass pipe. The fines formed during the test (prevented from escaping by a filter) are reported as attrition loss expressed as the percentage of the sample charged [359].

6. Reaction Networks and Mechanisms of Selected Catalytic Reactions on Solid Catalysts

As discussed in Section 2.3, a catalytic mechanism can be described by a catalytic cycle taking all elementary reaction steps and surface intermediates into account. For a complete description of a mechanism, exact knowledge of the reaction dynamics and energy-transfer processes is required. Investigations into these details are emerging only recently [28]. The maximum knowledge that can presently be obtained (with a few exceptions) is a quantitative analysis of experimentally determined kinetic parameters such as preexponential factors and activation energies for forward and backward reactions of elementary steps. A kinetic model can thus be established and reaction rates predicted. The necessary information is often obtained from surface science studies on model systems such as metal single crystals.

Frequently, reaction schemes are derived from product and intermediate distributions that can be observed in the fluid phase, often without any information on the nature of surface intermediates. These reaction schemes should be considered as reaction networks rather than mechanisms.

In the following, CO oxidation and NH_3 synthesis are discussed as reactions for which the mechanisms are known in significant detail at the atomic level. The discussion of reaction schemes ("mechanisms" and reaction networks) for several organic reactions follows.

6.1. Carbon Monoxide Oxidation

CO oxidation on noble metals (Pt, Pd, etc.)

$$CO + 1/2\,O_2 \longrightarrow CO_2 \tag{24}$$

occurs in catalytic reactors in automobiles and helps reduce air pollution. The reaction is relatively well understood, based on surface science studies. On Pd, dioxygen is chemisorbed dissociatively, while CO binds associatively [360], [361]. Molecular CO then reacts with atomic oxygen in the adsorbed state:

$$O_2 + 2* \longrightarrow O_{2,ads} \longrightarrow 2\,O_{ads} \tag{25}$$

$$CO + * \longrightarrow CO_{ads} \tag{26}$$

$$CO_{ads} + O_{ads} \longrightarrow CO_2 + 2* \tag{27}$$

Here $*$ denotes a free surface site and the subscript 'ads' indicates an adsorbed species. The reaction steps (25) – (26) suggest that CO oxidation is a Langmuir – Hinshelwood process in which both reacting species are adsorbed on the catalyst surface. The reverse of reaction (25), i.e., the recombination of two oxygen atoms is kinetically insignificant at temperatures below ca. 600 K. Possible Eley – Rideal steps (28) and (29), in which a gas-phase molecule reacts with an adsorbed species were found to be unlikely. Once CO_2 is formed according to step (26) or (29) it desorbs instantaneously.

$$CO + O_{ads} \longrightarrow CO_2 + * \tag{28}$$

$$2\,CO_{ads} + O_2 \longrightarrow 2\,CO_2 + 2* \tag{29}$$

Quantitative experiments led to a schematic one-dimensional potential energy diagram characterizing the elementary steps on the Pd(111) surface (Fig. 17). Most of the energy is liberated upon adsorption of the reactants, and the activation barrier for the combination of the adsorbed intermediates is relatively small; this step is only weakly exothermic, and the heat of adsorption (activation energy for desorption) of CO_2 is very low.

Figure 17. Schematic one-dimensional potential energy diagram characterizing the $CO + O_2$ reaction on Pd(111) [361]

The sequence of elementary steps (25) – (27) is quite simple. The overall kinetics, however, is not. This is due to the nonuniformity of the surface and the segregation of the reactants into surface domains at higher coverages. As a consequence, the reaction between the surface species CO_{ads} and O_{ads} can only occur at the boundaries between these domains. A simple Langmuir-Hinshelwood treatment of the kinetics is therefore ruled out, except for the special case of low surface coverages by CO_{ads} and O_{ads}, when these are randomly distributed and might be considered to a first approximation as being part of an ideal surface.

6.2. Ammonia Synthesis [45], [85], [179]

The ammonia synthesis reaction

$$N_2 + 3\,H_2 \rightleftharpoons 2\,NH_3 \qquad (30)$$

is exothermic and accompanied by a decrease in the number of moles. The reaction toward the target product NH_3 is therefore thermodynamically favored at low temperature and high pressure. The reaction is catalyzed by iron-based catalysts. Model experiments have been extensively carried out to elucidate the reaction mechanism by the surface science approach using iron single crystals.

The adsorption of N_2 on iron is slow and is characterized by a very low sticking coefficient (ca. 10^{-6}) and high activation energy [85]. Single-crystal surfaces of iron are reconstructed upon adsorption of nitrogen. Dinitrogen is dissociated above 630 K [363] and forms complex surface structures. These have been inferred to be surface nitrides with depths of several atomic layers [85]. Their composition is roughly Fe_4N. The corresponding bulk compound is thermodynamically unstable under conditions for which the surface structure is stable. The rate of dissociative adsorption of dinitrogen is structure-sensitive, the Fe(111) face being by far the most active, since the activation energy is the smallest and the rate of adsorption the highest [364]. The same crystal face is also the catalytically most active. These observations are consistent with the earlier suggestion [365] that dinitrogen adsorption is an activated process and that it is the rate-determining step in the catalytic cycle.

In contrast, the adsorption of dihydrogen on iron is fast and characterized by a high sticking coefficient (ca. 10^{-1}) and an extremely small activation barrier. The chemisorption is dissociative yielding covalently bonded H atoms which have high mobility on the iron surface.

Atomic nitrogen was shown to be the most stable and predominant chemisorbed species on Fe(111) after evacuation [360], [361], and it was inferred to be an intermediate in the catalytic reaction. Adsorbed dinitrogen could be excluded as a reactive intermediate. The involvement of adsorbed N atoms in the rate-determining step was also demonstrated by kinetics experiments [366]. Other less stable and less abundant surface intermediates include NH and NH_2 species.

Based on these results the following sequence of elementary steps was formulated (∗ denotes a surface site):

$$N_2 + 2* \longrightarrow 2\,N_{ads} \quad (31)$$

$$H_2 + 2* \longrightarrow 2\,H_{ads} \quad (32)$$

$$N_{ads} + H_{ads} \longrightarrow NH_{ads} + * \quad (33)$$

$$NH_{ads} + H_{ads} \longrightarrow NH_{2ads} + * \quad (34)$$

$$NH_{2ads} + H_{ads} \longrightarrow NH_3 + 2* \quad (35)$$

A schematic potential energy diagram for the catalytic cycle is shown in Figure 18. Decomposition of N_2 is exothermic, whereas the steps involved in the successive hydrogenation yielding NH_x species are endothermic. The addition of the first H atom is the most difficult step.

The promotion of the iron catalyst with potassium lowers the activation energy for dissociative N_2 chemisorption [367].

The sequence of elementary steps (31) – (35) was the basis for the microkinetic analysis discussed in Section 2.2.2, which permitted the prediction of overall reaction rates based on the kinetic parameters characterizing the individual elementary steps.

6.3. Acid – Base catalysis of Hydrocarbon Transformations

(reprinted from D. S. Santilli and B. C. Gates [368])

6.3.1. Introduction

The technological importance of surface-catalyzed hydrocarbon reactions has motivated years of effort to understand their mechanisms. But because of the difficulty of determining surface reaction intermediates, understanding of surface reaction mechanisms lags far behind that of solution reaction mechanisms, and what is known about the former is fragmentary and often largely based on presumed analogies with the latter, combined with results such as those from tracer experiments, kinetics experiments, and theoretical chemistry.

Catalysis by acids and bases generally proceeds via cycles involving hydrogen transfer reactions. In solution, solvent molecules such as water often play a role, e.g., by interacting strongly with reaction intermediates and/or by being donors or acceptors of protons. Reactions catalyzed by soluble acids or bases are also catalyzed by solid acids or bases, but the solid-catalyzed reactions usually take place in the absence of solvents and at much higher temperatures than are practical with solutions. When solid catalysts incorporate functional groups similar to those of soluble catalysts, there are close analogies between the two. For example, sulfonic acid groups in ion-exchange resins (used to catalyze the synthesis of methyl *tert*-butyl ether from isobutylene and methanol) act catalytically much like soluble toluenesulfonic acid.

When proton-donor groups are dissociated and hydrated so that (hydrated) H_3O^+ ions are present, then these are the catalytically active species, and the term *specific acid catalysis* is applied. Such catalysis is virtually the same in solution and near the surface of a hydrated solid acid such as an ion-exchange resin. Catalysis by OH^- is called *specific base catalysis*. On the other hand, when undissociated acid (or base) groups are the catalytic sites, the catalysis is called *general acid (or base) catalysis*. General acid catalysis, whether in solution or on a surface, is usually complex because a variety of unidentified species may be simultaneously present and catalytically active.

General acid catalysis predominates in solid acid catalysis. Because typical solid acids such as metal oxides incorporate both a spectrum of proton-donor groups such as OH groups (Brønsted acid sites) and a spectrum of electron-pair acceptor groups (Lewis acid sites) with various strengths, the catalytic sites often remain unidentified. Thus although there may be simple relationships between catalytic activity and easily measured properties characterizing acidity, they often do not provide much insight into the nature of the catalytic sites or the reaction mechanism. The same holds true for basicity and catalysis by bases. Thus the analogies between solution and surface acid (or base) catalysis are for the most part rather weak, and the mechanistic interpretations summarized here are simplified.

Figure 18. Potential energy diagram for the sequence of elementary steps of the ammonia synthesis reaction (energies in kJ mol^{-1}) [179]

6.3.2. Carbocations and Their Reactions

The key reaction intermediates in acid-catalyzed hydrocarbon reactions are carbocations [109], [370–375], the reactions of which are summarized below. Reactions proceeding by radical intermediates are ignored here, although they are important in hydrocarbon reactions catalyzed by acids at temperatures higher than those of the processes mentioned here.

6.3.2.1. Nature and Formation of Carbocations

Carbenium Ions. Hydrocarbons are weak bases, and the acid catalysts required for their conversion are relatively strong acids. The most important reactant classes include alkenes, aromatic hydrocarbons, and alkanes. Aromatics and alkanes are present in crude petroleum, and alkenes are formed as products of petroleum cracking. Solid acids are important catalysts for many large-scale conversions of these compounds. Alkenes and aromatics in the presence of a strong acid are converted in part into carbenium ions, which are intermediates in a variety of acid-catalyzed reactions, summarized below. In solution, carbenium ions are usually solvated or present in ion pairs, but, for simplicity, the carbenium ion structure alone is often written.

Carbenium ions form from alkenes and from aromatics by proton additions (Eq. 36) and from alkanes via carbonium ion intermediates (Eq. 37).

(36)

(37)

Much has been learned about the reactions of carbenium ions from their investigation in superacid solutions [373]. Superacids are combinations of Lewis and Brønsted acids, such as $HF + SbF_5$ or $FSO_3H + SbF_5$. In aprotic solvents, they are so strongly acidic that they are

capable of protonating alkenes almost entirely to give carbenium ions; the following reaction (Eq. 38) generating a carbenium ion is driven almost completely to the right.

$$R{-}CH{=}CH{-}R' + H^+ \longrightarrow R{-}\overset{+}{C}H{-}CH_2{-}R' \qquad (38)$$

Superacids have thus allowed investigations of the reactivities of carbenium ions in the near absence of alkenes. Complete conversion of alkenes to carbenium ions greatly simplifies matters because alkenes react with carbenium ions. Investigations with proton and ^{13}C NMR spectroscopy have provided a wealth of quantitative information about carbenium ion reactivity and, consequently, about mechanisms of catalytic conversion of hydrocarbons [109], [369]. This chemistry is a foundation for what follows.

The great proton-donor strengths of superacids are associated with reactions that stabilize protonated forms of the Brønsted acids [373]. For example, when FSO_3H is in the presence of SbF_5, $[FSO_3H_2]^+$ is formed; when HF is used with SbF_5, the superacidic proton donor is H_2F^+. These species can form because of the great stability of the anions $SbF_5(SO_3F)^-$ and SbF_6^-, with which they may be ion-paired.

Tertiary carbenium ions are much more stable than secondary carbenium ions, which are much more stable than primary carbenium ions. Calorimetric measurements have shown that the difference in stability between tertiary and secondary carbenium ions having the same carbon skeleton is about 54 kJ mol^{-1} [376]. The difference in stability between secondary and primary carbenium ions having the same carbon skeleton is greater than about 71 kJ mol^{-1}. Because entropy effects are expected to be negligible, the free energy differences correspond to the enthalpy differences. There are no significant differences in stabilizing effects attributed to different alkyl groups.

Quantum mechanical calculations have been done to help visualize how an alkene molecule interacts with acidic OH groups such as those present on the surfaces of metal oxides or zeolites [377], [378]. Basically, the π-electron cloud of the hydrocarbon interacts with the proton-donor group, and then the proton bound to the catalyst surface forms a bond to one carbon atom in a C=C moiety. The surface O–H bond is broken, and another oxygen atom of the surface forms a bond with the other carbon atom of the C=C moiety. Regardless of how this actually occurs, the result is a covalently bonded surface alkoxy species, which is regarded as an intermediate in numerous catalytic reactions (Scheme 1).

It is presumed that excited states of such alkoxy species are carbenium ion-like in behavior and are the transition states for catalytic reactions for which the alkoxy species are intermediates (Fig. 19) [379], [380]. The reactions of the carbenium ions are discussed below.

An alkane forms a carbenium ion through carbonium ion-like reactions, which are discussed below. This can result from interaction of an alkane with a proton to give a carbenium ion plus H_2 or a smaller carbenium ion plus an alkane. Altematively, a carbenium ion can form as a result of an interaction of an alkane with a carbenium ion:

1) Hydrogen transfer from an alkane to a carbenium ion, giving another alkane and another carbenium ion
2) Disproportionation of a carbenium ion to give a carbenium ion of a different carbon number

These are discussed below.

Carbonium Ions The interaction of an alkane with a superacidic proton donor can be written as in Scheme 2, whereby addition can occur across a C–C or a C–H bond. The product, a carbonium ion, has a three-center, two-electron bond [373]. Such a species must be strongly coordinated to the catalyst surface, and calculations have shown the permissibility of surface transition states such as those shown in Scheme 3 [381–383]. It is believed that concerted bond-breaking and bond-forming steps make the energetics favorable relative to the energetics of stepwise reactions.

6.3.2.2. Reactions of Carbenium Ions

The following sections describe the elementary steps undergone by carbenium ions, whatever their exact nature.

Scheme 1.

Figure 19. Energy diagram for conversion of alkoxy species into carbenium ion-like species

Scheme 2.

Intramolecular Reactions.

Hydride and Alkyl Shifts. The important reactions of carbenium ions include isomerizations proceeding by 1,2-hydride and 1,2-alkyl shifts, symbolized by H~ and CH_3 ~, respectively. The hydride shift is probably the most facile reaction of carbenium ions. Formally, it occurs as shown in Equation (39). Mechanistically, it may involve a three-membered (or larger) ring intermediate and a more or less symmetrical transition state involving concerted bond making and breaking (Scheme 4).

(39)

Scheme 3.

Scheme 4.

Carbenium ions equilibrate rapidly to give a distribution of isomers favoring the more stable highly substituted species.

Alkyl shifts involve the migration of alkyl groups, as shown formally in Equation (40) and Scheme 5.

(40)

The distribution of products is affected by the stabilities of the transition states by which they are formed, with tertiary being favored over secondary being favored over primary carbenium ions; vinyl and benzyl carbenium ions are also relatively stable. However, the formation of stable highly substituted species can be sterically inhibited, for example, by the confining pores of zeolites, as discussed below. The rates of alkyl shifts are less than the rates of hydride shifts, and they may be competitive with hydride transfer and β-scission, depending on the nature of the carbenium ions and other interacting species.

The alkyl shift mechanisms probably involve protonated cyclopropyl (or larger-ring) intermediates, as shown in Scheme 6 [384–386].

Combinations of these elementary steps account for reactions such as skeletal isomerization of a tertiary octyl cation (Eq. 41), which proceeds via a hydride shift followed by a methyl shift (Eq. 42). The intermediate is a secondary carbenium ion, which, in solution, is about 54 kJ mol^{-1} less stable than the tertiary reactant ion. Because the activation energy barrier for a

hydride or methyl shift is roughly 5 kJ mol^{-1}, the activation energy for the overall reaction in solution is about 60 kJ mol^{-1}.

Scheme 5.

(41)

(42)

Carbenium ion rearrangements leading to a change in the degree of branching are not accounted for by simple hydride and alkyl shifts. For example, the isomerization shown in Equation (43), which leads from a carbenium ion with a single branch to one with two branches, does not proceed via a sequence of hydride and methyl shifts, because it would involve a highly unstable primary carbenium ion. The accepted mechanism for a branching rearrangement involves an intermediate incorporating a protonated cyclopropane ring, which is much lower in energy than a primary carbenium ion. Carbenium ion rearrangements leading to changes in the degree of branching are believed generally to proceed via such intermediates [371], [384–386].

(43)

β-Elimination. When an adsorbed carbenium ion reacts to give back the proton to the surface with desorption of an alkene, the reaction is the reverse of protonation of an alkene by the surface. This reverse reaction is a β-elimination, which may proceed as in Equation (44).

(44)

This reaction is favored at high temperatures (≥ 800 K) and competes with β-scission (described below). At lower temperatures, intermolecular reactions (described below) can intervene.

β-Scission. An important reaction of carbenium ions is β-scission, the breaking of a carbon – carbon bond located β to the charged carbon atom, which occurs in catalytic cracking. The reaction occurs formally as in Scheme 7 (it may occur in concert with a hydride shift to form more stable carbenium ions). Again, a concerted

Scheme 6.

Scheme 7.

Scheme 8.

reaction can be written for a possible mechanism (Scheme 8).

The reaction generates an alkene and another carbenium ion. The rate depends on the relative stabilities of the reactant and product carbenium ions. When both are tertiary, the reaction is fast, faster than a branching rearrangement but slower than a nonbranching rearrangement [371]. The β-scission step may be as fast as some intermolecular reactions such as hydride transfer (described below), but with branched alkanes in the reactant mixture and with carbenium ions with < 7 carbon atoms, hydride transfer can be much faster.

Cyclization. Formally, the reaction is written as in Equation (45). Products formed by cyclization reactions include carbonaceous deposits (coke).

(45)

Intermolecular Reactions. The reactions here involve carbenium ions as Lewis acids reacting with alkanes, alkenes, and aromatics.

Reactions with Alkanes: Hydride Transfer. Carbenium ions are Lewis acids and capable of abstracting hydride ions, shown formally as in Equation (46). The alkane is converted into a carbenium ion and vice versa. The bimolecular reaction is extremely rapid when both reactant and product cations are tertiary and much less rapid when a tertiary cation reacts to give a secondary cation. The mechanism is not known, but it might proceed as shown in Equation (47).

(46)

(47)

Alternatively, it has been proposed [387] that this reaction may also proceed through carbonium ion-like intermediates **1**, perhaps similar to those proposed for the alkane-proton reaction. However, free carbonium ions are unlikely to form, and if this reaction proceeds through carbonium ion-like species, Equation (46) is more plausible.

In principle, hydride transfer involving alkenes can also take place much as hydride transfer involving alkanes takes place.

Disproportionation. Formally, this occurs as shown in Equation (47), in which fragments of the carbon skeletons of the interacting alkane and carbenium ion are exchanged. Mechanistically, what might take place is shown in structure (48).

(48)

(49)

Reactions with Alkenes: Dimerization. The alkene adds to the carbenium ion to form a larger carbenium ion (Eq. 49). This is the reverse of β-scission and takes place in alkylation reactions. It is thermodynamically favored at low temperatures (alkylation is carried out at subambient temperatures), whereas β-scission is favored at high temperatures (cracking is carried out at temperatures of roughly 800 K).

(50)

Reactions with Aromatics. Addition of aromatics to carbenium ions is illustrated by Equations (51) and (52), using the reaction of Equation (50).

(51)

(52)

6.3.3. Catalytic Reactions Involving Carbocation Intermediates (see also [388])

Alkene Oligomerization and Polymerization [389]. After formation of a carbenium ion, repeated addition reactions can occur, forming longer carbenium ions (Eq. 49). These carbenium ions can undergo β-elimination to give

desorbed alkenes as products (Eq. 44), or they can undergo hydride transfer with hydrocarbons to form alkanes (Eq. 45).

Isomerization [390]. Double bond migration in alkenes results from protonation to form a carbenium ion, one or more hydride shifts, and then β-elimination to give the desorbed alkene. As in solution, *cis – trans* isomerization can also occur, as a result of bond rotation in the carbenium ion or alkoxy species formed from the alkene, followed by β-elimination.

Skeletal isomerization (e.g., *n*-pentane $\rightarrow$ isopentane; *p*-xylene $\rightarrow$ *o*-xylene) involves formation of the carbenium ion (Scheme 3 (a) or Eq. 45 for alkanes; Eq. 36 for unsaturates) followed by alkyl shifts (Eq. 40), perhaps concomitant with hydride shifts (Eq. 39) to avoid formation of primary carbenium ions, and finally hydride transfer (Eq. 45), leading to the desorbed alkane. (Primary carbenium ion formation can also be avoided if the reactions proceed via protonated cyclopropyl intermediates.) The process is represented by Scheme 9.

Disproportionation reactions can also lead to isomerization (Eq. 53) [391], [392].

(53)

Alkene isomerization can take place by protonation to give a carbenium ion, followed by alkyl shifts and β-elimination to give the rearranged alkene. Aromatic isomerization can take place by carbenium ion formation (Eq. 36) followed by hydride (Eq. 39) and alkyl (Eq. 40) shifts leading to ring expansion or contraction, as shown in Scheme 10. The reactions lead to changes in the type of alkyl group or the location of the alkyl group on the ring. Product formation results from β-elimination (Eq. 44). Alternatively, aromatics can isomerize intermolecularly via transalkylation, as described below.

Ring expansion or contraction of cycloalkanes takes place as a carbenium ion is formed (Scheme 3 (a) or Eq. 45), followed by alkyl shifts, as shown in Scheme 5 (b). However, the mechanism may be more complex than what is shown here [393]. For example, concerted hydride shifts may occur to avoid formation of primary carbenium ions (Scheme 9). Furthermore, protonated pseudo-cyclopropyl rings can form (Scheme 6).

Cyclization of alkenes takes place by carbenium ion formation followed by carbon-carbon bond formation (Eq. 44). Once an alkane is converted into a carbenium ion (Scheme 3 (a); Eq. 45), the same steps can follow.

Cracking [394]. Mechanisms of many hydrocarbon reactions catalyzed by acidic surfaces are interpreted within the framework of the chemistry stated in the preceding sections. One of the most important of these is catalytic cracking, whereby hydrocarbons are converted into smaller hydrocarbons in the presence of zeolite-containing acid catalysts at temperatures of roughly 800 K. Besides gas oil cracking and residuum cracking, processes in this class include shape-selective dewaxing. Reactants include alkanes, alkylaromatics, and products of cracking, including alkenes.

Alkanes and cycloalkanes crack via a variety of combinations of steps. Alkanes are activated as stated above. They undergo both bimolecular (i.e., carbenium ion or classical) cracking [395] and unimolecular (i.e., carbonium ion or Haag-Dessau) cracking [395–398], with the former dominating at temperatures less than about 700 K. Unimolecular cracking of an alkane is initiated as the alkane is protonated by the catalyst. Some solid acids (superacids) may even be able to protonate alkanes at temperatures much less than those of cracking processes.

If addition of the proton is across a C–C bond, the resultant carbonium ion can crack to give an alkane and a carbenium ion, and the latter can undergo a β-elimination to give an alkene. This mechanism predicts equimolar yields of the alkane and alkene products, which have been observed, for example, for cracking of *n*-butane catalyzed by HZSM-5 at low conversions [397]. If addition of the proton is across a C–H bond, the resultant carbonium ion splits out H_2 and a carbenium ion, which can undergo β-elimination to give an alkene. In cracking of *n*-butane catalyzed by HZSM-5, H_2 and butenes were observed in equimolar yields at low conversions, consistent with this mechanism [399].

Scheme 9.

Scheme 10.

Instead of β-elimination, the carbenium ion formed by cracking of the carbonium ion may undergo β-scission in either of these mechanisms (Scheme 7).

The alkenes produced by unimolecular cracking, especially in zeolites, are readily protonated by the catalyst to give carbenium ions. This may be a negligible side reaction at very low conversions, but otherwise it can become a dominant pathway of cracking, whereby carbenium ions undergo bimolecular reactions with alkanes. This leads to hydride transfer and disproportionation reactions, as shown in Equations (46) and (48). Disproportionation can lead directly to cracked products (Eq. 48).

In this bimolecular cracking mechanism, a C_6 molecule interacting with a C_3 carbenium ion can crack to give C_4 and C_5 fragments without giving C_1 and C_2 fragments (Eq. 54). In contrast, in cracking by the unimolecular mechanism, in which a proton is added across a C–C bond, all these products are formed [Scheme 2 (b)].

(6 + 3 → 4 + 5) (54)

In bimolecular cracking, the final carbenium ion fragment shown leaving as an alkene in Equation (44) can instead undergo hydride transfer with an alkane (Eq. 46) and leave as an alkane. This

step activates another feed alkane molecule; the carbenium ion is thus a chain carrier, and the process is cyclic (catalytic), as shown in Figure 20. Thus bimolecular cracking becomes an important route at conversions greater than a few percent; it is especially favored at lower temperatures with zeolite catalysts at conversions that are not very low.

Figure 20. Schematic catalytic cycle for the bimolecular cracking of alkanes

Note that alkane cracking is a very complex process. The alkane interacts with protons and a wide variety of carbenium ions (which form from the alkane). Any of the hydrocarbon bonds can interact with the acidic site. This makes it difficult to unravel any mechanism. Furthermore, many other reactions accompany cracking, including isomerization, disproportionation, and C-C bond forming. A number of recent investigations have led to a fairly complete statement of the complex product distributions and relative rates of the elementary reactions [395–404]. The most incisive cracking experiments have been done with zeolite catalysts having low concentrations of proton-donor groups, such a HZSM-5; catalyst deactivation is minimal with this zeolite.

Alkylation [405], [406]. Aromatic alkylation [407] takes place by addition of a carbenium ion to the aromatic ring, as shown in Equation (52), followed by β-elimination (Eq. 44). Alternatively, one could envisage addition of an alkene to a carbenium ion formed from the aromatic hydrocarbon, but in practice this is unimportant because carbenium ions are formed much more readily from alkenes than from aromatics because aromatics lose the stabilization of resonance energy upon addition of a proton, whereas alkenes do not.

Alkane alkylation, for example, the industrially important formation of octanes (among other products) from the reactions of 1-butene with isobutane occurs via formation of the carbenium ion by protonation of the alkene, activation of the alkane by hydride transfer (Eq. 46), addition of the alkene to the carbenium ion (Eq. 50), hydride transfer from the isobutane to release the dimer and form another carbenium ion, and so forth [407]. The steps are shown in the schematic catalytic cycle of Figure 21.

Practical alkylation is catalyzed by liquid HF or H_2SO_4, and research with solid alkylation catalysts has been motivated by environmental concerns associated with the liquid acids. So far, there is no good solid acid alternative to the liquid acids; the solids undergo rapid deactivation.

Transalkylation of Aromatics. This industrially applied reaction [408] leads to the transfer of alkyl groups between aromatic rings; one application is transalkylation of toluene to give xylenes. The transalkylation of xylene to give toluene and trimethylbenzene is shown in Scheme 11.

The aromatic is activated to give a carbenium ion **2** and, after hydride shifts, this adds to another aromatic. Hydride shifts (Eq. 39) and β-scission (Scheme 7) combine to produce the transfer. However, steric constraints can force this reaction to proceed by an otherwise higher energy route. This involves formation of the carbenium ion **3**, β-scission to release the aromatic (Scheme 7), addition of the carbenium ion R^+ that is thereby formed to another aromatic molecule, and so on (Scheme 12).

These mechanisms can also lead to aromatic isomers, for example, if the toluene product undergoes transalkylation with xylene in Scheme 11.

Aromatization of Alkanes and Alkenes [409]. A carbenium ion can cyclize (Eq. 45)

Figure 21. Schematic representation of the mechanism of 1-butene – isobutane alkylation, represented as a catalytic cycle. Numerous side reactions are omitted for simplicity.

Scheme 11.

followed by β-elimination (Eq. 44) and/or hydride transfer reactions (Eq. 46) to form an aromatic compound, as shown in Scheme 13. The R^+ species come from alkenes adding to proton acidic sites. Thus the net reaction converts alkenes into alkanes and converts naphthenes (cyclic alkanes) into aromatics. This is an important class of reaction that is catalyzed efficiently by zeolites in catalytic cracking processes.

Coke Formation [410]. The term coke refers to high molecular mass hydrocarbon residues that form on surfaces of catalysts and contribute to catalyst activity loss [370], [411]. The mechanism of coke formation is complex

Scheme 12.

Scheme 13.

and only partially understood, and continuing research has the goal of understanding of the nature of coke and the mechanisms of its formation. Different reactants can form different types of coke on the surface of a given catalyst and, on different catalysts, the same reactants give different cokes.

Coke generation may proceed via carbenium ion formation followed by repeated addition reactions with unsaturates to form large species (Eqs. 50 and 52), which can block acidic sites and fill pores. Cyclization, reactions along with β-elimination and hydride transfer can lead to polymers, polycyclics, and graphitic species.

Steric Influence of the Catalyst. Catalysts such as zeolites, with pore diameters about equal to molecular dimensions, can exert strong steric influences in catalysis; the phenomena are referred to as shape-selective catalysis [412–418]. These phenomena are discussed in Section 2.1.8.

6.4. Metal Catalysis of Hydrocarbon Transformations

(reprinted from D. S. Santilli and B. C. Gates, ref. [368], p. 1132)

A great variety of hydrocarbon reactions proceed on surfaces of metal catalysts, and exten-

sive research has been done with the goal of understanding their mechanisms. Some of the most thoroughly investigated reactions are occurring in naphtha reforming and catalyzed by transition metals such as platinum. Hydrocarbon reactions catalyzed by surfaces of transition metals include alkene and arene hydrogenation, alkene isomerization, homologation, and hydrogenolysis, and alkane isomerization, dehydrogenation, hydrogenolysis, and dehydrocyclization. Recent reviews provide summaries of mechanistic interpretations of these metal-catalyzed hydrocarbon reactions [419–427].

This subject is less than well developed and summarized here in only the briefest form. Many of the published mechanisms are no more than postulated reaction pathways. The subject is so fragmented that systematic statements of what is known are largely lacking. Mechanistic information has been determined from results of tracer experiments and kinetics as well as from the effects of changes in product distribution resulting from changes in reactant structure, catalytic metal, structure of the surface of a given metal, and metal particle size and composition, among others. For the most part, structures of proposed reaction intermediates are no more than hypothetical, with details of bonding between reactant and surface typically being unknown. Theoretical chemistry has not yet had much impact on this subject. Researchers have often drawn on assumed parallels with organometallic chemistry to formulate postulates of mechanisms of metal-surface-catalyzed reactions.

Skeletal Isomerization of Hydrocarbons. The literature of metal-catalyzed skeletal isomerization reactions was summarized by GAULT [419], who used ^{13}C-labeled molecules extensively in attempts to elucidate reaction pathways and infer mechanisms. Numerous such reactions are believed to proceed via cyclic intermediates that are postulated to be metallacycles, although other intermediates are important also. Cyclizations take place, for example, by 1,5-ring closure; subsequent breaking of a C–C bond may give an isomerized acyclic product [427]. When the hydrocarbon structure does not allow formation of a C_5 cyclic intermediate, rearrangements may take place by a so-called bond shift mechanism. Alternatively, 1,6-ring closure may also take place, and when followed by subsequent dehydrogenations, it leads to aromatic products.

Many suggestions have been offered as to the nature of the postulated intermediates and their bonding to catalyst surfaces, but none is well justified. Many of the postulated surface intermediates are dehydrogenated.

Hydrogenation of Alkenes [428]. Hydrogenation of alkenes, especially ethylene, has often been investigated in attempts to understand the reaction mechanism. Because of the simplicity of the reactant molecules, this reaction was long considered to be a good candidate as a reaction offering a relatively simple and easily elucidated mechanism. This early expectation has not been borne out, however, and successive series of experiments have led to recognition of greater and greater degrees of subtlety in the mechanism. We cite here a recent investigation that provides details of the mechanism of ethylene hydrogenation catalyzed by a Pt(111) single crystal [430]. The work demonstrates the advantages of a new surface-science technique, infrared-visible sum frequency generation spectroscopy.

Vibrational spectra were measured with the catalyst in the working state; the method allows determination of spectra of surface species that are not influenced by the composition of the gas phase. The spectra indicate the formation of several surface species formed from ethylene [430]: These are ethylidyne **1**, di-σ-bonded ethylene **2**, and a species inferred to be π-bonded ethylene, presumed to interact with a single surface platinum atom **3**.

During catalytic reaction at 295 K and pressures of a fraction of 1 bar, the spectra indicated the presence on the Pt surface of all three species. Only the π-bonded ethylene was involved as a catalytic intermediate under these conditions. The other two species were only spectators on the surface (although they could be hydrogenated under more severe conditions). The di-σ-bonded species could be converted

Scheme 14.

Scheme 15.

Scheme 16.

into the alkylidyne, and the two competed for surface sites. However, the π-bonded ethylene did not compete for these sites; it was present on the surface at various concentrations depending on the reaction conditions. The authors [430] concluded that the π-bonded ethylene was the only significant hydrocarbon reaction intermediate under these conditions. Because π-bonded ethylene is presumed to be bonded to a single Pt atom of the surface, its identification as a reaction intermediate is consistent with the observation that ethylene hydrogenation is a structure-insensitive reaction [430]. If it is assumed that there is an analogy between the surface-catalyzed reaction and the Wilkinson hydrogenation catalyzed by mononuclear organorhodium phosphine complexes, then it is expected that the π-bonded intermediate would be converted into a σ-bonded ethyl group and then into ethane; however, there is no evidence of these postulated intermediates on the working catalyst surface.

Hydrogenolysis and Homologation of Alkenes. A recent investigation of the reactions of 3,3-dimethyl-1-butene catalyzed by silica-supported ruthenium at temperatures ≥ 373 K [431] illustrates some current mechanistic ideas and the importance of organo-metallic chemistry as a foundation for interpreting mechanisms of surface-catalyzed reactions. The predominant reaction of 3,3-dimethyl-1-butene was hydrogenation. Slower accompanying reactions were homologation and hydrogenolysis, which proceeded at approximately equal rates. The homologation products were 2,2-dimethylpentane and 2,2,3-trimethylbutane in a 10 : 1 ratio, as well as traces of 4,4-dimethyl-1-pentene. The hydrogenolysis products were neopentane, methane, isobutylene, and isobutane, as well as traces of other alkenes and alkanes. In addition, slow skeletal isomerization occurred, giving the nonprimary products 2,3-dimethyl-1-butene and 2,3-dimethyl-2-butene at 373 K.

The product distributions at low conversions were used to infer mechanisms of the homologation and hydrogenolysis reactions. The most plausible mechanism of the hydrogenolysis of 3,3-dimethyl-1-butene was suggested [429] to be one in which the C–C cleavage step is a deinsertion of a methylene fragment from a Ru-neopentyl moiety (Scheme 14). An alternative, proceeding through a metallacyclic intermediate, would involve a γ-hydrogen elimination, which was impossible because the γ-carbon atom in the alkyl chain has no hydrogen atom. The absence of significant formation of 2-methyl-2-butene is consistent with the absence of reaction according to Scheme 15.

Scheme 14 also accounts for isobutylene product. The same mechanism also accounts for the principal homologation products (Scheme 16: R.E. = reductive elimination; β-H = β-hydride elimination) [431].

These mechanisms are no more than formalisms that are consistent with known organometallic chemistry and account for the observed products. The bonding of the intermediates to the ruthenium surfaces is not well understood.

6.5. Selective Hydrocarbon Oxidation Reactions

Selective hydrocarbon oxidation reactions include several important classes of heterogeneously catalyzed reactions, which find large-scale industrial application for the synthesis of bulk chemicals. Reviews on the mechanisms of selective hydrocarbon oxidation [145], oxidative dehydrogenation of alkanes [429], ammoxidation of alkenes, aromatics and alkanes [61], and epoxidation of alkenes [432] are available. Here, some mechanistic aspects of the epoxidation of alkenes and of the ammoxidation of alkenes are discussed.

6.5.1. Epoxidation of Ethylene and Propene [432], [433]

The epoxidation of ethylene by dioxygen is catalyzed by silver metal and yields ethylene oxide (→ Ethylene Oxide), an important intermediate for the synthesis of glycols and polyols.

Total oxidation of the reactant and the target product limit the selectivity of the process. Scheme 17 shows the three competing reactions.

Scheme 17.

The catalyst therefore must be tuned such that the optimal selectivity for ethylene oxide is achieved. The active phase consists of large Ag particles supported on low surface area α-Al_2O_3 promoted by alkali metal salts. A beneficial effect is also obtained by adding chlorine-containing compounds such as vinyl chloride to the reaction feed. Unter reaction conditions this additive is readily combusted on silver, and chlorine is adsorbed on the metal surface.

Oxygen can be adsorbed on transition metals in general and on silver in particular in three different states: (1) molecular dioxygen, (2) adsorbed atomic oxygen, and (3) subsurface atomic oxygen [433]. Molecular oxygen is stable on an Ag(111) surface at temperatures below ca. 220 K. It dissociates at higher temperatures. Oxygen dissociation occurs at high-coordination sites, since at least two neighboring metal atoms must be available. It has been shown that ensembles with a minimum of five silver atoms are required [434], [435]. Oxygen atoms adsorbed originally on the external silver metal surface may move to subsurface lattice positions. Subsurface oxygen atoms have been proved to form on transition metals including Rh, Pd, and Ag [436]. The maximum oxygen coverage on silver surfaces is one oxygen atom per silver atom, corresponding to the composition of AgO [433].

The presence of subsurface oxygen atoms reduces the electron density on adjacent silver atoms. Hence, oxygen atoms adsorbed on the external surface which share bonds to silver surface atoms with subsurface oxygen atoms become highly polarizable. When exposed to ethylene, the interaction of the surface oxygen atoms with the π electrons of ethylene leads to a flow of electron density from the surface oxygen atom to the positively charged surface silver atom [437]. The surface oxygen atoms behave chemically as electrophilic oxygen atoms, which preferentially react with the part of the reactant molecule having the highest electron density. This situation is most likely at high oxygen coverages, consistent with the experimental observation that the epoxidation selectivity is dramatically enhanced by increasing oxygen coverage [438]. Scheme 18 illustrates this scenario [432]. At low oxygen coverages the density of subsurface oxygen atoms is also reduced so that the polarizability of oxygen atoms adsorbed on the external surface is reduced. Consequently, these oxygen atoms behave as nucleophilic oxygen atoms and tend to interact preferentially with hydrogen atoms of the ethylene molecule, thus leading to total oxidation. This situation is schematically shown in Scheme 19 [432]. Therefore, epoxidation selectivity must decrease with decreasing oxygen coverage. The fact that vacant silver sites exist in the vicinity of an adsorbed oxygen atom at low coverage (see Scheme 19), is also detrimental.

Scheme 18.

Scheme 19.

The influence of alkali metal and chlorine modifiers is complex. The effect of chlorine is twofold: (1) it suppresses vacant silver sites, and (2) it enhances the electron deficiency of silver. The latter effect is due to the ability of chlorine to also occupy subsurface positions [439] and thus to adopt the role of subsurface oxygen as illustrated in Scheme 20 [432]. These effects

improve the initial selectivity r_1/r_2 (r_i denotes a reaction rate, see Scheme 17). The overall selectivity is also reduced by subsequent combustion of the epoxide (r_3 in Scheme 17), particularly at high conversions. The combustion of the epoxide is induced by the residual acidity of the α-Al_2O_3 support. The presence of alkali metal reduces the density of acid sites and thus has a beneficial effect on selectivity by blocking reaction step r_3.

Scheme 20.

The rate-limiting step of the epoxidation reaction is the dissociative chemisorption of dioxygen. Alkali metal compounds enhance the dissociation rate of dioxygen by reducing the activation barrier, and consequently the alkali metal modifier enhances the epoxidation rate as its coverage increases [432]. Interestingly, when a chlorine-modified catalyst is promoted by alkali metal compounds, the reaction rate decreases, and this is suggestive of an enhancement of the steady-state concentration of adsorbed chlorine, which leads to site blocking. Therefore, there is a very subtle interplay between the two additives which must be carefully controlled to optimize conversion and selectivity of the ethylene epoxidation reaction.

The epoxidation of *propene* with dioxygen is unfavorable because of the enhanced reactivity of the methyl group for nucleophilic attack. Activation of the methyl group leads to the allyl or combustion of the propylene epoxide. Alternative oxidants are hydrogen peroxide or hydroperoxide (→ Propylene Oxide, Chap. 4.2.). The reaction of propene with hydrogen peroxide yields the target product propylene epoxide and water (Eq. 55).

(55)

The preferred catalyst for this reaction is titanium-silicalite-1 (TS-1) (see Section 3.1.1), in which four coordinate Ti^{4+} plays the decisive role [440]. Although the exact nature of the reaction intermediate is not known yet, hydrogen peroxide may coordinate nondissociatively to a Lewis acidic tetrahedral Ti^{4+} site as shown in Scheme 21. This induces electron deficiency on the oxygen atoms of the peroxides, which is favorable for epoxidation. An analogous reaction path has been proposed for the homogeneous epoxidation of propene by peroxides [432].

Scheme 21.

6.5.2. Ammoxidation of Alkenes [61], [441]

In ammoxidation, ammonia reacts with a reducible organic molecule, most frequently an alkene, alkane, or aromatic, in the presence of dioxygen to yield nitriles (e.g., Eq. 56).

$$2\,CH_2{=}CRCH_3 + 2\,NH_3 + 3\,O_2 \longrightarrow 2\,CH_2{=}CRCN + 6\,H_2O \qquad (56)$$

The ammoxidation of an alkene is a six-electron oxidation that produces an unsaturated nitrile and water. The reaction is related to the four-electron oxidation of alkenes (Eq. 56) [74] producing unsaturated aldehydes and water, and to

the two-electron oxydehydrogenation of alkenes to dialkenes and water (Eq. 57) [74].

$$CH_2{=}CRCH_3 + O_2 \longrightarrow CH_2{=}CRCHO + H_2O$$

$$2\,CH_2{=}CHCH_2CH_2R + O_2 \longrightarrow 2\,CH_2{=}CHCH{=}CHR + 2\,H_2O \quad (57)$$

Catalysts for these reactions are complex mixed metal oxides containing variable-valence elements (see Section 3.1.1), the ammoxidation catalysts typically being the most complex. These materials possess redox properties, i.e., they can readily be reduced by ammonia and reoxidized by dioxygen present in the gas phase. It is the lattice oxygen of the catalyst which reacts with ammonia and the hydrocarbon, and the reduced solid is reoxidized by gas-phase oxygen (Mars – van Krevelen mechanism [442], see also [145]).

The most important alkene ammoxidation is that of propene to acrylonitrile (Sohio Acrylonitrile Process, Eq. 58; see also → Acrylonitrile, Chap. 5.) [429]

$$2\,CH_2{=}CH{-}CH_3 + 2\,NH_3 + 3\,O_2 \longrightarrow 2\,CH_2{=}CHCN + 6\,H_2O \quad (58)$$

Molybdates and antimonates can be used as catalysts for this reaction. The active sites are thought to have bifunctional nature [61], [443], [444]. A generalized catalytic cycle for alkene ammoxidation is shown in Figure 22 [61]. Ammonia is proposed to interact first with the bifunctional active site generating an ammoxidation site. The alkene coordinates to this site to form an allylic intermediate. After several rearrangements and oxidation steps, the surface intermediate is transformed into the nitrile, which subsequently desorbs. A reduced surface site is thus formed, which is restored to its original fully oxidized state by lattice oxygen O^{2-}, which is provided by adjacent reoxidation sites. These sites then dissociate dioxygen to lattice oxygen. The newly formed lattice oxygen then diffuses to the oxygen-deficient reduced surface site, from where vacancies simultaneously penetrate through the lattice of the solid to the reoxidation sites. Clearly, these sites must communicate with each other via a common solid-state lattice which is capable of facile transport of electron, anion vacancies, and lattice oxygen [61]. As an example, the proposed bifunctional active site of Bi_2MoO_6 (see Section 3.1.1) is schematically illustrated in Figure 23 [158]. The various functionalities were assigned to specific elements and to specific lattice oxygen positions. Bridging oxygen atoms Bi–O–Mo are considered to be responsible for α-hydrogen abstraction from the alkene, while oxygen atoms associated with Mo are responsible for oxygen (Mo=O) and nitrogen (Mo=NH) insertion into an allylic intermediate. The oxygen dissociation and its reduction to lattice oxygen is assumed to occur in the region of high electron density generated by the two lone pair electron orbitals of Bi–O–Bi sites. More easily reducible elements than Bi are Fe, Ce, U, and Cu, which are components of more complex, multicomponent catalysts (see Section 3.1.1) [61]. As an illustration of the mechanisms of ammoxidation and selective oxidation of propene, Figure 24 shows the proposed catalytic cycles for the two reactions [445].

6.6. Hydroprocessing Reactions [46], [212], [213], [447], [448], [449]

(see also → Oil Refining, Chap. 4.)

Hydroprocessing treatment, including hydrodesulfurization (HDS), hydrodenitrogenation (HDN), hydrodeoxygenation (HDO), hydrometalation (HDM), hydrogenation, and hydrocracking, are among the largest industrial processes in terms of catalyst consumption. Crude petroleum contains particularly organosulfur and organonitrogen compounds, which are most abundant in heavy petroleum fractions. These contaminants must be removed for environmental reasons. The reactions take place in the presence of H_2 at high temperatures (ca. 600 – 700 K) and pressures of 500 kPa to 1 MPa. Because of the lower reactivity of organonitrogen compounds as compared to organosulfur compounds, the reaction conditions are more severe for HDN than for HDS.

Catalysts for hydroprocessing are highly dispersed metal sulfides (mainly MoS_2, but also WS_2) supported on γ-Al_2O_3. The materials are promoted by cobalt or nickel, depending on application.

Although the detailed mechanisms have not yet been elucidated, significant progress in understanding the chemistry of the various hydroprocessing reactions at a molecular level has

Figure 22. Generalized mechanistic cycle for alkene ammoxidation

Figure 23. Schematic representation of the active site of Bi_2MoO_6 [446]
O′ = Oxygen responsible for α-H abstraction; O″ = Oxygen associated with Mo; reponsible for oxygen insertion into the allylic intermediate; □ = Proposed center for O_2 reduction and dissociative chemisorption.

Figure 24. Mechanism of selective ammoxidation and oxidation of propene over bismuth molybdate catalysts [445]

been made [46], [212], [213], [448], [449]. In the following, however, the focus is on reaction networks of several hydroprocessing reactions with pseudo-first-order rate constants for individual reaction steps.

The organosulfur compounds in petroleum include sulfides, disulfides, and aromatics (including thiophene, benzothiophene, dibenzothiophene, and related compounds). Benzo- and dibenzothiophene are predominant in heavy fuels. The reaction network for hydrodesulfurization of dibenzothiophene, a representative member of organosulfur contaminants in fuel, is shown in Figure 25 [450]. Hydrogenation and hydrogenolysis take place in parallel. The latter reaction is essentially irreversible and leads to the formation of H_2S and biphenyl. At low H_2S concentrations in the feed, the sulfide catalysts are highly selective for hydrogenolysis. The selectivity, however, drops sharply as the H_2S concentration in the feed increases.

Hydroprocessing reactions accompanying hydrogenation and hydrodesulfurization include hydrodenitrogenation, whereby organonitrogen compounds in the feed react with H_2 to give NH_3 and hydrocarbons. As an example, a reaction network for the hydroprocessing of quinoline is shown in Figure 26 [447]. The supported metal sulfide catalysts are much less selective for nitrogen removal than for sulfur removal.

7. Application of Catalysis in Industrial Chemistry

Modern industrial chemistry is predominantly based on catalytic processes, of which 80 – 85 % are heterogenously catalyzed. The processes include the production of inorganic and organic chemicals, petroleum refining, production of synthetic fuels, pollution control, and energy conversion.

7.1. Important Inorganic Reactions

Inorganic catalytic reactions represent different key steps in the production of more than a million metric tons of inorganic chemicals.

Production of hydrogen (→ Hydrogen, Chap. 4.1.) is based on the water gas shift (WGS) reaction:

$$CO + H_2O \rightleftharpoons H_2 + CO_2$$

The WGS reaction is reversible and exothermic. To increase the hydrogen content in the product it is thus desirable to perform the WGS reaction at low temperature. However, for technical reasons the reaction is performed industrially in two steps. The first step proceeds at high temperature (HTS) and partly converts CO to CO_2 and H_2. In the second step the remaining of CO reacts at low temperature (LTS) [451].

One source of carbon monoxide is methane or naphtha steam reforming performed on α-alumina supported Ni.

$$CH_4 + H_2O \longrightarrow CO + 3\,H_2$$

Ammonia synthesis (→ Ammonia) from hydrogen and nitrogen:

$$N_2 + 3\,H_2 \rightleftharpoons 2\,NH_3$$

The production of ammonia is one of the largest catalytic processes in the world and has a strategic position as the key to nitrogen chemistry. The synthesis reaction is exothermic and reversible. Low temperature and high pressure facilitate ammonia formation [45], [452].

Nitric acid production (→ Nitric Acid, Nitrous Acid, and Nitrogen Oxides) is based on the catalytic oxidation of ammonia with atmospheric oxygen:

$$NH_3 + 1.25\,O_2 \longrightarrow NO + 1.5\,H_2O$$

The key reaction is exothermic and irreversible at 1070 – 1170 K. It is performed at slightly elevated pressure on a suitable catalyst. Subsequent production steps do not require a solid catalyst:

$$NO + O_2 \longrightarrow 2\,NO_2$$

$$3\,NO_2 + H_2O \longrightarrow 2\,HNO_3 + NO$$

Nitric acid is one of the most important industrial chemicals in terms of tonnage [183].

Production of sulfuric acid (→ Sulfuric Acid and Sulfur Trioxide) includes heterogenously catalyzed oxidation of SO_2:

$$SO_2 + 1/2\,O_2 \rightleftharpoons SO_3$$

$$SO_3 + H_2O \longrightarrow H_2SO_4$$

Figure 25. Reaction network for hydrodesulfurization and hydrogenation of dibenzothiophene catalyzed by sulfided $Co-Mo/Al_2O_3$ at 570 K and 10 MPa [450]
Numbers next to the arrows represent the pseudo-first-order rate constants in units of L/(g of catalyst · s) when the H_2S concentration is very small. Addition of H_2S markedly decreases the selectivity for hydrodesulfurization.

Figure 26. Reaction network for hydrogenation and the hydrogenolysis of quinoline catalyzed by sulfided $Ni-Mo/\gamma\text{-}Al_2O_3$ at 620 K and 3.5 MPa [447]
Numbers next to the arrows represent the pseudo-first-order rate constants in units of L/(g of catalyst · s) when the H_2S concentration is small but sufficient to maintain the catalysts in the sulfided forms.

SO_2 oxidation is a reversible and exothermic reaction. On an industrial scale it is carried out at 670 – 820 K. The worldwide production amounts to 150×10^6 t/a [240].

Sulfur recovery (Claus process) according to the following reactions (→ Sulfur, Chap. 4.):

$$2\,H_2S + O_2 \longrightarrow S_2 + 2\,H_2O$$

$$2\,H_2S + SO_2 \rightleftharpoons 3/2\,S_2 + 2\,H_2O$$

The second reaction is reversible and is performed in practice between 470 – 570 K. The Claus process is used by petroleum refineries to recover sulfur from H_2S obtained by hydrodesulfurization. Hundreds of Claus plants are in operation worldwide with individual capacities of 2000 t/d or more [121].

Solid catalysts applied in the above-mentioned processes are summarized in Table 11.

Table 11. Catalysts applied in some processes in inorganic reactions [451]

Process	Catalyst	Ref.
Hydrogen production by WGS		[451]
HTS	$Cr_2O_3 - Fe_2O_3$	
LTS	CuO – ZnO	
Ammonia synthesis	Fe_3O_4 (K, Ca, Mg, Al oxides)	[45], [452]
Ammonia oxidation	Pt/Rh wire gauze	[183]
SO_2 oxidation	V_2O_5 (K_2SO_4)	[240]
Claus process	Al_2O_3 or TiO_2	[121]

7.2. Important Organic Reactions

While the application of solid catalysts in inorganic reactions is 1imited to a few large-scale processes, their use in the production of organic chemicals is very broad. More than two hundred different catalysts are applied currently in the manufacture of organic intermediates, fine chemicals, and pharmaceuticals [453].

Important catalytic processes for the production of organic chemicals include the following reaction classes:

Hydrogenations (→ Hydrogenation and Dehydrogenation) are typical reversible and exothermic reactions. They are performed mainly at lower temperatures in the liquid or in the vapor phase at atmospheric or elevated hydrogen pressure in the presence of supported metallic catalysts containing, e.g., Ni, Co, Cu, Pt, Pd. Some examples of catalysts used in total hydrogenations [454] are collected in Table 12.

Table 12. Catalysts applied in total hydrogenations [454]

Process	Catalyst
Olefins → paraffins (olefinic gasoline or diesel)	Ni – or Pt – alumina
Benzene → cyclohexane	Ni – alumina, Ni – kieselguhr, Pt – alumina
Naphthalene → tetra- and decahydronaphthalenes	Ni – alumina, Ni – kieselguhr, Pt – alumina
Phenol → cyclohexanol	Ni – kieselguhr, Pd – kieselguhr
Aldehydes and ketones → alcohols	Ni – kieselguhr, Ni (Cu,Co) – kieselguhr, Cu (Ba,Mn) – chromites
Nitro compounds → amines	Pd – kieselguhr, Co – kieselguhr
Nitriles → amines	Co – kieselguhr, Cu – chromites
Carboxylic acid esters → alcohols (Henkel, Lurgi)	Cu (Ba,Mn) – chromites

Of major industrial importance is the hydrogenation of olefins in gasoline and diesel fractions.

The hydrogenation of benzene to cyclohexane (→ Cyclohexane) is the first step in the manufacture of adipic acid (→ Adipic Acid, Chap. 5.) and finally of synthetic fibers, e.g., Nylon 66. In a standard process, a Ni catalyst is used. In a new technology, realized by IFP, a homogeneous Ni catalyst [$Ni^{2+}/Al(Et)_3$] is used [455].

The manufacture of synthetic fibers (Nylon 6), based on caprolactam starts with the hydrogenation of phenol to cyclohexanol.

The hydrogenation of carboxylic esters is carried out under severe conditions (470 – 570 K, 200 – 300 bar hydrogen pressure).

A special class of reactions are selective hydrogenations of unsaturated or functionalized hydrocarbons. This process plays an important role in the removal of alkyne compounds from $C_2 - C_5$ cuts produced by naphtha pyrolysis [428], [456].

The direct hydrogenation of benzene to cyclohexene is a new process, commercialized in 1995 [457].

The partial saturation of double bonds in fats and oils provides the possibility to obtain variable products in the food industry. The world ca-

pacity of fat-hardening plants in 1993 was about 66×10^6 t [459].

Table 13 summarizes selective hydrogenation reactions together with the catalyst used in each particular case.

Table 13. Catalysts applied in selective hydrogenations [453], [456], [458], [459]

Process	Catalyst
Acetylene → ethylene	Pd – alumina, Pd(Ag) – alumina
Diolefins → olefins (1,3-butadiene, isoprene, cyclopentadiene)	Pd – alumina, Pd – silica
Benzene → cyclohexene	Ru – alumina
Fats and edible oils (fat hardening)	Ni – kieselguhr, Ni(Zr) – kieselguhr
Unsaturated aldehydes → saturated aldehydes	Cu – alumina, Raney Pd
Unsaturated aldehydes → unsaturated alcohols	Rh(Sn) – silica, Pt(Fe,Co) – silica

Another special class of organic reactions involves the hydrogenation of CO. The examples presented in Table 14 show the large variety of reactions and products formed in CO hydrogenation.

Table 14. Catalysts applied in CO hydrogenations and related reactions [460], [462], [464]

Process	Catalyst
CO methanation $CO + 3\,H_2 \rightleftharpoons CH_4 + H_2O$	Ni – alumina, Ru – alumina
Methanol synthesis $CO + 2\,H_2 \rightleftharpoons CH_3OH$	$CuO - ZnO - Al_2O_3$
Hydroformylation (Oxo synthesis) $CO + H_2 + \text{olefin} \rightarrow \text{aldehyde}$	
(Aldox, Shell)	$[HCo(CO)_3PBu_3]$
(Lp oxo, Davy McKee, Union Carbide)	$[HRh(CO)(PPh_3)_3]$
Fischer – Tropsch synthesis	Fe oxides (K)
Methanol carbonylation $CH_3OH + CO \rightarrow CH_3COOH$ (Monsanto)	$[Rh(CO)_2I_2]^-$

One possibility to remove CO impurities from hydrogen, used in ammonia synthesis, is its conversion to methane. Above 500 K and at a pressure of 10 MPa the application of Ni-based catalysts is common. Below 470 K, Ni catalysts cannot be used because of $[Ni(CO)_4]$ formation. Ru-containing materials are the low-temperature catalysts of choice [265].

The world production capacity of methanol (→ Methanol) reached more than 26×10^6 metric tons in 1995. At present plants using low-pressure technology (5 – 7 MPa) operate at up to 490 – 530 K with Cu – Zn – Al catalysts. Older high-pressure plants using $ZnO - Cr_2O_3$ catalysts have mainly ceased operation [460].

Three Fischer – Tropsch synthesis plants (2×10^6 t/a) are currently operating in South Africa. With fixed-bed technology, the main products are waxes (→ Waxes, Chap. 5.). In fluidized-bed reactors mainly gasoline and a variety of oxygen-containing compounds are produced (→ Coal Liquefaction, Chap. 2.2.) [461].

The production of aldehydes from olefins (→ Oxo Synthesis) is one of the most important processes of homogeneous catalysis. The older oxo process, realized by Shell, is using Co-catalyst and operates at 100 bar pressure. The newer LP-oxo process based on Rh catalysts performs at only 2 MPa [462], [463].

The carbonylation of methanol to acetic acid [464] currently dominates all other processes for acetic acid production (→ Acetic Acid).

Dehydrogenation (→ Hydrogenation and Dehydrogenation) is the reverse reaction of hydrogenation. Dehydrogenations are endothermic and are facilitated at high temperature and low pressure. From the industrial view point important dehydrogenations are those of $C_3 - C_4$ aliphatic hydrocarbons to produce olefins or dienes [218]. The dehydrogenation of ethylbenzene (→ Styrene) [465] and of some aliphatic alcohols [466] are also industrially important. Catalysts applied in dehydrogenations are summarized in Table 15.

Table 15. Catalysts applied in industrial dehydrogenations [218], [465], [466]

Process	Catalyst
$C_3 - C_4$ (iso-)Alkanes → olefins	
Catofin (Houdry)	$Cr_2O_3 - Al_2O_3$ (K), $Cr_2O_3 - ZrO_2$
Oleflex (UOP)	Pt(Sn) – alumina
STAR (Phillips)	$Pt(Sn) - ZnAl_2O_4$, $MgAl_2O_4$
Butane → butadiene (Catadiene, Houdry)	$Cr_2O_3 - Al_2O_3$ (K)
$C_{10} - C_{14}$ Alkanes → linear olefins	
(Pacol-Olex)	Pt(Sn) – alumina
Ethylbenzene → styrene	Fe oxides (K, Cr, Mo, Ce)
2-Butanol → methylethylketone	ZnO, Cu – kieselguhr
Cyclohexanol → cyclohexanone	ZnO – CaO, Cu – kieselguhr

Table 16. Catalysts applied in some industrially important elimination and addition reactions [189], [389], [405], [467], [469]

Process	Catalyst
Hydration	
Propene → 2-isopropanol	H_3PO_4 – kieselguhr
Dehydration	
2-Phenylethanol → styrene	alumina
Methanol → dimethylether	alumina
Alkylation	
Benzene → Ethylbenzene	
Monsanto	$AlCl_3$ (liq. phase)
Alkar (UOP)	BF_3 – alumina
Mobil-Badger	Zeolites (ZSM-5)
Benzene → isopropylbenzene (UOP)	H_3PO_4 – kieselguhr
Dealkylation	
Diethylbenzene → ethylbenzene, benzene	alumosilicate
Disopropylbenzene → isopropylbenzene, benzene	alumosilicate
Additions	
Isobutene + CH_3OH → methyl *tert*-butyl ether (MTBE)	Acid ion exchanger (Amberlyst)
Isopentene + CH_3OH → methyl *tert*-amyl ether	Acid ion exchanger (Amberlyst)
Oligomerization	
Propene → C_3H_6 (dimers), C_6H_{12} (trimers), $C_{12}H_{24}$ (tetramers)	H_3PO_4 – kieselguhr, zeolites (ZSM-5, mordenite), Amberlyst

The highly endothermic dehydrogenation of lower alkanes can be facilitated by the introduction of oxygen to burn the formed hydrogen and produce the required heat. These so-called *oxidative dehydrogenations* are exothermic and can be realized at lower temperatures. On an industrial scale, the oxidative dehydrogenation of *n*-butane to butenes on supported Sn, Bi, Co, and Ni oxides and of butenes to butadiene (→ Butadiene) over Cu and Ni phosphates were realized [218].

Elimination and Addition Reactions. There are various reversible organic reactions such as hydration – dehydration, alkylation – dealkylation, etc. Catalysts applied in these reactions have mainly acidic properties, for example solid phosphoric acid, aluminosilicates, zeolites, etc. [467]. The industrial importance of dehydrations and hydrations has decreased. An exception is methanol dehydration, the first step in the Mobil fuel process.

The production of ethylbenzene (→ Ethylbenzene) and isopropylbenzenes by alkylation and the addition of methanol to isobutene or isopentene are multimillion-ton processes. Some examples of elimination and addition reactions [189], [389], [405], [468], [469] are presented in Table 16.

Oxidations. Catalytic oxidations of hydrocarbons occupy a prominent place in the modern chemical industry, because they represent the easiest route for the functionalization of hydrocarbon molecules [145].

Oxidation of organic compounds in the liquid phase is a traditional area of homogeneous catalysis [470], [471]. The common feature of these reactions is a high selectivity. Some established industrial processes and applied catalysts are summarized in Table 17.

Table 17. Catalysts applied in liquid-phase oxidation [470], [471]

Process	Catalyst
n-Butane → acetic acid	Cr, Mn, Co, Ni acetates, naphthenates
Cyclohexane → cyclohexanol/one	Co naphthenate
Toluene → benzoic acid	Co, Mn acetates
Benzoic acid → phenol	Cu, Mn benzoates
p-Xylene → terephtalic acid	Mn acetate
Acetaldehyde → acetic acid anhydride	Co acetate
Ethylene → acetaldehyde (Wacker process)	$PdCl_2$ – $CuCl_2$
Propene → acetone	$PdCl_2$ – $CuCl_2$
Ethylene + CH_3COOH → vinyl acetate	$PdCl_2$ – $CuCl_2$

Table 18. Solid catalysts applied in vapor-phase oxidation [145], [146], [432], [472], [473]

Process	Catalyst
Ethylene → ethylene oxide	Ag(Cs) – alumina
Propylene + H_2O_2 → propylene oxide (Enichem)	Ti silicalite
Propene → acrolein	Mo, Bi, Fe oxides
Acrolein → acrylic acid (Mitsubishi Ryon, Nippon Kayku)	Mo, V oxides
Isobutene → methacrolein	Mo, Bi oxides
Methacrolein → methacrylic acid (Nippon Kayku, Nippon Shokubai)	Mo, V, heteropoly acids
o-Xylene, naphthalene → phthalic anhydrate	
(Alusuisse)	V_2O_5 – Al_2O_3
(Nippon Shokubai)	V_2O_5 – TiO_2
n-Butane → maleic anhydrate (Lummus Crest)	$(VO)_2P_2O_7$ (Fe)
Benzene → maleic anhydrate	V_2O_5 – MoO_3 (P, Ni)
Methanol → formaldehyde	Fe molybdate + MoO_3

In the past 15 years several oxidation processes utilizing solid catalysts and operating in the vapor phase were installed in the chemical industry, e.g., oxidation of propene or isobutene to unsaturated aldehydes or acids and the production of phtalic and maleic anhydrates based on the oxidation of hydrocarbons etc. [145], [146], [432], [472], [473]. Table 18 lists some important processes.

Ammoxidations. The interaction of ammonia with hydrocarbons and oxygen in the presence of a suitable catalyst results in the formation of the corresponding nitrile. Acrylonitrile, benzonitrile and nitriles obtained in the reaction with *o*-, *m*- and *p*-xylenes achieved a high industrial importance [61].

In the reaction of cyclohexanone with NH_3 and H_2O_2, cyclohexanone oxime is formed [474]. Catalysts applied in various ammoxidations are described in Table 19.

Table 19. Catalysts applied in the ammoxidation of hydrocarbons [61], [474]

Process	Catalyst
Propene → acrylonitrile (Sohio)	Bi – molybdate (Fe,Ni,Co)
Isobutene → methacrylonitrile	Bi – Sb molybdate (Fe)
Toluene → benzonitrile	Bi – P molybdate (Fe,Ni,Co) on SiO_2
o-, *m*-, *p*-Xylene → phthalonitriles	Sb, V, Bi, Fe oxide on TiO_2
Cyclohexanone + H_2O_2 → cyclohexanone oxime (Enichem)	Ti silicate

Dimerizations, Metathesis, Polymerizations. The high demand of various higher olefins, especially in the range $C_6 - C_{12}$, initiated intensive research in the field of dimerization. IFP developed the dimersol process for converting propene into hexenes or 1-butene into octenes [475]. In the SHOP process, $C_{10} - C_{18}$ α-olefins are synthesized from ethylene [217].

Alkene metathesis is a catalytic reaction in which olefins are converted into a new product by rupture and reformation of the carbon – carbon bonds. For example, isopentene is produced on industrial scale from isobutene and *n*-butene [217].

Major achievements in the area of catalytic polymerization in the past led to the development of a new branch of the chemical industry [245], [476]. In 1995 the production of polyethylene and polypropylene amounted to 44×10^6 t (→ Polyolefins). Catalysts applied in these reactions are listed in Table 20.

Table 20. Catalysts applied in dimerizations, metathesis, and polymerization [217], [245], [475], [476]

Process	Catalyst
Propene → hexenes	
1-Butene → octenes (Dimersol, IFP)	$Ni^{2+} - AlEtCl_2$
Ethylene → $C_{10} - C_{18}$ 1-olefins (SHOP, Shell)	bis(cyclooctadienyl)Ni
Isobutene + 2-butene → isopentene + propene	
$(CH_3)_2C{=}CH_2 + 2\text{-}C_4H_8 \rightarrow (CH_3)_2C{=}CHCH_3 + C_3H_8$ (Phillips)	$MoO_3 - SiO_2$, $WO_3 - SiO_2$, $Re_2O_7 - Al_2O_3$
Cyclohexene + ethylene → 1,7-cyclooctadiene	$Re_2O_7 - Al_2O_3$
Ethylene → polyethylene (HDPE, Phillips)	
370 K, 70 bar	$CrO_3 - SiO_2$
Ethylene → polyethylene (LDPE, Ziegler – Natta, Solvay)	$TiCl_4 - Al(Et)_3$
2 – 10 bar	$TiCl_3 - AlEt_2Cl - MgCl_2$
Propene → polypropylene	$TiCl_3 - AlEt_2Cl - MgCl_2$

7.3. Petroleum Refining (see also → Oil Refining)

The integration of chemical, and especially of catalytic processes into crude oil upgrading, created a new industrial branch called petroleum refining. The main task of this industry is to ensure high yield and good quality of liquefied petroleum gas (LPG), gasoline, diesel fuel, jet fuel, etc. The major processes in catalytic refining are catalytic cracking, hydrotreating, reforming, and hydrocracking [477].

The primary objective of catalytic cracking, currently performed exclusively with fluidized-bed technology (FCC), is to increase the yield of high-octane gasoline from crude oil. FCC process conditions are 750 – 810 K and atmospheric or slightly reduced pressure [394].

The hydrotreating processes include hydrodesulfurization (HDS), hydrodenitrogenation (HDN), hydrodeoxygenation (HDO), and demetalation. In these processes N, S, O, and metals such as V and Ni are removed from petroleum fractions mainly at 570 – 670 K and 2 – 4 MPa hydrogen pressure [46], [212], [230].

The main purpose of reforming is to increase the octane number of gasoline by isomerization of alkanes and naphthenes and above all by the conversion of these hydrocarbons into aromatics. It is usually performed at 720 – 820 K and slightly elevated pressure [47].

Hydrocracking was developed for the conversion of relatively heavy oil feedstocks into lighter transport fuel products at 570 – 720 K and 5 – 10 MPa hydrogen pressure. It is performed in one or two stages [478].

Other processes run by modern refineries are alkylation [406], isomerization [386], dewaxing [478], and etherification (MTBE and TAME production) [189].

Table 21 lists typical catalysts used in petroleum refining.

Table 21. Catalysts applied in some processes in petroleum refining [47], [394], [477]

Process	Catalysts
Fluid catalytic cracking (FCC)	ultrastable (US) Y zeolite in aluminosilicate matrix, US Y zeolite + ZSM-5 + aluminosilicate
Hydrotreating (HDS, HDN, HDO)	$Co-MoO_3-Al_2O_3$, $Ni-WO_3-Al_2O_3$
Catalytic reforming	
UOP	Pt(Sn) – alumina
Chevron	Pt(Re) – alumina
EXXON	Pt(Ir) – alumina
Hydrocracking	
single-stage	$Ni-MoO_3-Y$ zeolite – alumina, $Ni-WO_3$ – alumina
two-stage	$Ni-MoO_3-Y$ zeolite – alumina, Pd – or Pt – mordenite – alumina
Dewaxing	$Ni-WO_3$ – alumina (HF), Ni-ZSM-5, Pt – zeolite β
Alkylation of isobutane with C_3-C_4 olefins (commercial process, UOP, etc.)	HF/BF_3, H_2SO_4
Chevron (pilot stage)	SbF_5-SiO_3
Isomerization of C_4-C_6 alkanes	
Penex (UOP)	Pt – alumina (HCl-activated)
Hysomer (Shell)	Pt – H mordenite

7.4. Production of Synthetic Fuels

The energy crisis in the early 1970s initiated intensive research into direct and indirect synthesis of fuels.

An example of a direct route is coal liquefaction based on catalytic coal hydrogenation. The H-Coal process (→ Coal Liquefaction, Chap. 3.9.1.) developed by Hydrocarbon Research is carried out at 670 – 720 K and 14 – 28 MPa hydrogen pressure in the presence of $Co-MoO_3$ catalysts [479], [480].

In the Exxon H-donor solvent process (→ Coal Liquefaction, Chap. 3.9.4.) the hydrogen transfer from solvent to coal proceeds at 670 K and 1 – 4 MPa. Solvent recovered from the liquefied coal is saturated with hydrogen in the presence of an $Ni-MoO_3$ catalyst and recycled.

The indirect route is represented by Fischer – Tropsch (FT) synthesis and above all by the Mobil process for converting methanol to gasoline (MTG) on a shape selective zeolite (ZSM-5).

The FT synthesis was discussed in Section 7.2.

Analogous to the FT synthesis is the SMDS process (Shell Middle Distillate Synthesis) established quite recently in an operation in Malaysia. The process consists of two basic steps: Heavy paraffins synthesis from CO and H_2 over a Zr-promoted Co catalyst and selective hydrocracking of heavy paraffins to middle distillate over a zeolitic catalyst [481].

The Mobil MTG process is based on the catalytic conversion of methanol to hydrocarbons over a shape-selective zeolite (ZSM-5) [482]. The conversion process consists of a series of consecutive reactions: first dimethyl ether is formed, followed by the formation of alkenes, alkanes, and aromatics. In fixed-bed reactors, methanol conversion takes place at 620 – 685 K and about 0.2 MPa over alumina and ZSM-5. The MTG process was commercialized in New Zealand, where it is used to convert offshore natural gas via methanol into high-octane gasoline. In the fluid-bed MTO process (methanol to olefins) the main products at 740 – 780 K are olefins, which can be oligomerized over ZSM-5 to jet fuel.

7.5. Pollution Control

7.5.1. Mobile Sources

Road traffic is one of the major sources of CO, hydrocarbons, and NO_x emissions. In 1995 more than 600 million vehicles were on the roads

world-wide, mainly in North America, Europe, and Japan.

Since 1975 – 1980 catalytic converters have been standard equipment of gasoline driven engines in the USA, Western Europe, and Japan (→ Automotive Exhaust Control).

At present, predominantly three-way catalysts are installed in cars. The heart of the catalytic converter is a cylindrical cordierite monolith having 62 channels per square centimeter. This structure is coated with a thin layer of washcoat consisting of a mixture of inorganic oxides such as Al_2O_3, CeO_2, LaO_2 etc. In the washcoat precious metals such as Pt and Rh (5 – 20 : 1) are dispersed. Instead of cordierite monoliths, metall supports are sometimes applied [198].

The emissions are removed by the following catalytic reactions taking place in the temperature range 570 – 770 K:

$$C_mH_n + (m + 0.25\,n)\,O_2 \longrightarrow m\,CO_2 + 0.5\,n\,H_2O$$

$$2m\,H_2O + C_mH_n \longrightarrow m\,CO_2 + (2m + 0.5\,n)\,H_2$$

$$CO + H_2O \longrightarrow CO + H_2$$

$$CO + NO \longrightarrow 0.5\,N_2 + CO_2$$

$$NO + H_2 \longrightarrow 0.5\,N_2 + H_2O$$

$$CO + 0.5\,O_2 \longrightarrow CO_2$$

Since 1991, catalytic converters have been also installed in passenger cars with diesel engines in the European Community. Emissions such as CO, aliphatic and aromatic hydrocarbons, aldehydes, and soot present in the exhaust gas are oxidized on a catalyst to CO_2 and H_2O. The catalyst consists of a cordierite monolith covered by a oxide washcoat and precious metals such as Pt or Pd.

The removal of NO_x from the exhaust gases of diesel or lean burn engines is difficult because of the high concentration of oxygen. The consumption of reducing agents, e.g., H_2, CO, or olefins, would be too high. However, catalytic NO decomposition to N_2 and O_2 is technically feasible. Suitable catalysts are Cu-containing ZSM-5 or oxides such as Co_3O_4, CuO, NiO, Fe_2O_3, and ZrO_2 [483].

7.5.2. Stationary Sources

Fossil fuels such as coal, oil, gas, and others are burnt or gasified for energy conversion. In Western European countries and Japan measures have been implemented since 1980 for reducing emissions, especially of NO_x from power plants.

One method to remove NO_x from exhaust gases of power plants, industrial boilers, and gas turbines is based on selective catalytic reduction (SCR) with ammonia in the presence of oxygen:

$$4\,NO + 2\,NH_3 + O_2 \longrightarrow 4\,N_2 + 6\,H_2O$$

Catalysts applied are mainly monoliths with 70 – 100 cm length, a cross section of 15 × 15 cm, and various numbers of channels. Industrial catalysts consist mainly of V_2O_5 supported on TiO_2. They operate in the presence of SO_2 at 470 – 670 K [210].

7.5.3. New Processes in Environmental Catalysis

The cleaning of the air from road tunnels and car parks requires CO oxidation at ambient temperature. Au on Co_3O_4 is highly active [484].

The high concentration of ozone in the recycle air of silicon chip factories is diminished by O_3 decomposition on Pd alumina catalysts at 420 K [485].

The removal of various odors from exhaust air, produced by bakeries, fish-smoking factories, coffee roasters, etc. is carried out on monolith Pt-alumina catalysts at 470 – 520 K [485].

7.6. Energy Conversion

7.6.1. Fuel Cells

Chemical energy is converted to electrical energy in fuel cells (→ Fuel Cells) by using solid catalysts on both the anode and the cathode. Fuel cells were developed and successfully applied, e.g., as a source of power in spacecraft and in some specical road vehicles. Till now various cells were tested, but only H_2/O_2 cells in the form of PAFC (phosphoric acid fuel cells) and PEMC (proton exchange membrane cells) are of technical relevance, especially modules producing 40 – 1200 kW [486].

The reaction of hydrogen on the anode

$$H_2 \rightleftharpoons 2\,H^+ + 2\,e^-$$

is catalyzed by Pt/Pd or Pt/Ru alloys. The latter is less sensitive to CO, while hydrogen for fuel cells is mainly produced by methane steam reforming:

$$CH_4 + H_2O \rightleftharpoons 3\,H_2 + CO$$

$$CO + H_2O \rightleftharpoons H_2 + CO_2$$

Catalysts for the oxygen reduction proceeding on the cathode:

$$0.5\,O_2 + 2\,H^+ + 2\,e^- \longrightarrow H_2O$$

are Pt or Pt – V alloy finely dispersed on a carbon support. PAF cells operate at 290 – 370 K and 0.1 – 0.6 MPa pressure [486].

Recent developments have shown that methanol fuel cells can be an attractive and realistic alternative.

7.6.2. Catalytic Combustion

Flameless combustion is a process in which the fuel reacts with oxygen on a catalyst surface providing CO_2, H_2O, and thermal energy. This process proceeds at much lower temperatures (1270 – 1570 K) than conventional combustion, and hence less NO_x (< 5 ppm) is formed [487]. Conventional catalysts consist of ceramic or metal monoliths covered by alumina stabilized with barium oxide and bearing finely dispersed precious metals, particularly Pt and Pd [487].

8. Technology of Catalytic Processes

8.1. Catalytic Reactors [488–492]

The development of a catalytic process involves the search for the catalyst and the appropriate reactor, and typically occurs in a sequence of steps at different levels. Small-scale reactors are used for screening to determine the optimal catalyst formulation. Since catalyst development and sequential screening is a slow and cost-intensive process, *fast-throughput techniques* [493–496] which permit parallel testing of small amounts of catalyst in microreactor systems are presently attracting great interest and are being developed with significant emphasis. The preparation of new or improved catalyst formulations is mainly empirical but can be aided by knowledge-based (expert) systems or molecular design [497–499].

Small-scale reactors are also used for establishing reaction networks and for determination of the reaction macrokinetics and selectivities, which are required for the optimization of the overall process. These studies are preferentially carried out under ideal conditions. The requirements for such *ideal reactors* are (1) good contact between reactants and catalyst; (2) no limitations caused by heat and mass transport inside and outside the catalyst particles; and (3) good description of reactor characteristics. These conditions can be achieved by plug flow or well-stirred tank reactors (see Section 8.1.1) which must guarantee well-defined residence times and residence-time distributions under isothermal conditions. Channeling of the fluid partially bypassing catalyst particles and uneven flow distributions must be avoided. In three-phase reactors, even distributions of gaseous and liquid reactants over the solid catalyst must be ensured.

Once a promising catalyst is found and reaction networks and macrokinetics of the target reaction are known, testing typically is continued in larger scale (bench and/or pilot) reactors for determination of catalyst lifetime and of the influence of process variables such as temperature, pressure, composition, and impurities in the reactant feed. Ultimately the scale-up to commercial plant dimensions will be performed [499].

Approximate dimensions of tubular reactors (see Section 8.1.1) for various applications on different scale are summarized in Table 22.

8.1.1. Classification of Reactors [113], [488], [490]

Catalytic reactors can be classified by their mode of operation under steady-state or transient conditions or on their mode of contacting/mixing of reactants and solid catalyst.

Typical *steady-state reactors* are packed-bed tubular reactors under continuous flow conditions, either plug flow or mixed flow. In an ideal tubular reactor ideal mixing takes place in the

Table 22. Approximate dimensions of tubular catalytic reactors

Scale	Diameter	Length	Mass of catalyst
Laboratory Microreactors	0.5 cm	0.5 – 1 cm	0.1 – 1 g
Laboratory Bench Scale Reactors	1.0 – 3.0 cm	10 – 30 cm	10 – 200 g
Pilot	5 – 7.5 cm	60 – 100 cm	50 – 100 kg
Plant	0.5 – 5 m	5 – 20 m	10 – 100 tons

radial direction, but there is no mixing in the axial direction. Plug flow is attained in this case. *Plug flow reactors* can be operated either in integral or differential mode. In the latter case, single-pass experiments in small-scale reactors provide the data for differential conditions required for analysis of the reaction kinetics. As an alternative, the effluent from the differentially operating reactor can also be recycled externally or internally, thus approaching a well-mixed reactor system, the continuous-flow *stirred tank reactor* (CSTR). Without inlet and outlet feed a continuous recycle flow results, characteristic of a *batch reactor* in which the feed composition changes with time (transient conditions as opposed to steady-state conditions). The catalyst must not necessarily be kept in a packed bed but can be suspended in the liquid or gaseous fluid reactant mixture. In the fluidized-bed mode, the solid catalyst consisting of fine powder (particle diameter 10 – 200 µm) is kept in motion by an upward gas flow (*fluidized-bed reactor*, see Section 8.1.3). If the fluid is a liquid the catalyst can be suspended easily in a CSTR by efficient stirring (*slurry reactor*, see Section 8.1.3). In so-called *riser reactors*, catalyst material is continuously introduced into and removed from the reactor with the reactant and product feeds.

Batch and semi-batch reactors operate under transient conditions. Discontinuous step or pulse operation necessarily results in transient conditions.

Several catalytic reactor types are schematically shown in Figure 27. *Tubular fixed bed reactors* (A) have an inlet flow $\dot{n}_0$ and an outlet flow $\dot{n}$ of the reactant-product mixture. The *adiabatic fixed-bed reactor* is shown in Figure 27 B. *Multitube fixed-bed reactors* (C) are used for highly exothermic reactions such as the oxidation of *o*-xylene to phthalic anhydride. The principle of a CSTR is demonstrated as D. A *fluidized-bed reactor* with catalyst recirculation is sketched in E. A *slurry CSTR reactor*is schematically shown in F. An alternative for three-phase reactions (gas – liquid – solid) is the *packed bubble column* or *slurry reactor* (G). Discontinuous batch reactors with internal and external recycling operating under transient conditions are depicted as H and I, respectively.

8.1.2. Laboratory Reactors [488], [489]

A compilation of laboratory reactors and their operation mode is given in Figure 28.

As indicated in Table 22, laboratory reactors are small-scale reactors. Steady-state fixed-bed tubular flow reactors are most frequently used for catalyst testing and determination of the reaction kinetics on the laboratory scale. These reactors are favored because of the small amounts of catalyst required, the ease of operation, and the low cost. Stirred tank reactors (e.g., with fixed or rotating basket) and batch suspension reactors are less frequently used. Provided that heat- and mass-transfer limitations can be neglected under the operating conditions in a tubular flow reactor, the catalyst bed is isothermal, and the pressure drop across the catalyst bed is negligible, the reaction rate can be determined from the mass balance for a component *i*. This is usually verified in microreactors operating under differential conditions. The *reaction rate* per unit mass r_W (mol s^{-1} kg^{-1}) is then given by Equation (59):

$$\frac{dx_i}{d\left(\frac{W}{F_i^0}\right)} = -\nu_i r_W, \tag{59}$$

where x_i is the conversion of component *i*, ν_i its stoichiometric coefficient, *W* the catalyst mass (kg), and $F_i{}^o$ the molar rate of component *i* at

the reactor inlet (mol s^{-1}). The ratio W/F_i° is the space – time.

Ancillary techniques in laboratory units for catalyst testing such as generation of feed streams, product sampling are discussed in [501].

A valuable laboratory pulse reactor (transient operation) is the *TAP reactor* (TAP = *temporal analysis of products*). Pulses containing small amounts of reactants (10^{13} – 10^{17} molecules/pulse) are injected into the evacuated reactor containing the catalyst bed. The reactant/product molecules leaving the reactor (response signal) are analyzed by mass spectroscopy with a time resolution $< 100\,\mu$s. This approach permits the study of surface pro-

Figure 28. Classification of laboratory reactors

cesses on solid catalysts such as adsorption, reaction, and desorption, and reaction mechanisms and kinetic models can be established [502–504].

8.1.3. Industrial Reactors [113], [490]

Various types of industrial reactors and their operation mode are listed in Figure 29.

Catalytic Fixed-Bed Reactors [505–507]. In the chemical industry fixed-bed reactors are the standard type of reactors for heterogeneously catalyzed gas-phase reactions (two-phase reactors). Fixed catalyst beds can be realized in various ways. Randomly packed beds (deep beds) require catalyst particles having different shapes such as spheres, cylinders, rings, flat disk pellets, or crushed material of a defined sieve fraction. The geometries and dimensions of the catalyst particles are dictated by pressure drop and heat- and mass-transfer considerations. The use of monolithic catalysts significantly reduces the pressure drop across the catalyst bed. This type of catalyst is employed for example for automobile exhaust gas purification and for the removal of nitrogen oxides from tail gases of power stations.

Fixed-bed reactors can be operated under adiabatic or nonadiabatic conditions. Adiabatic reactors can be applied for reactions with low heats of reaction such as gas purification. They consist of a cylindrical tube in which the catalyst is packed on a screen and is traversed in axial direction (Fig. 27 B). This design is particularly suitable when short residence times and high temperatures are required. In this case a fixed bed of large diameter and small height (5 – 20 mm) is used (shallow bed). As an example, for ammonia oxidation in nitric acid plants the fixed bed consists of several layers of platinum wire gauze

Figure 29. Classification of industrial reactors

with bed diameters up to several meters. This type of reactor is limited to small catalyst volumes. The radial flow concept is preferred when large amounts of catalyst are required [505]. In this reactor type, the catalyst is charged in the annular space around an axially located tube. The reactants are traversing radially, either from the inside or from the outside of perforated plate rings. Because of the low pressure drop, smaller catalyst pellets (4×4 or 3×3 mm) can be used in this reactor type.

Only limited conversions can be achieved by adiabatic reactors because of the necessary control of the adiabatic temperature change. Multistage reactors consisting of several sequential adiabatic stages which are separated by interstage heat exchangers have therefore been introduced.

Nonadiabatic operation can be achieved with fixed-bed reactors which are cooled or heated through the reactor walls. Efficient heat exchange results in so-called isothermal reactors. A typical example is the multitubular reactor schematically shown in Fig. 27 C, which is used for highly exothermic and temperature sensitive reactions (e.g., *o*-xylene oxidation) with, e.g., salt melts as heat-transfer media.

Autothermal reactors can favorably be applied for exothermic and temperature sensitive reaction systems. The conventional reactor design consists of an adiabatic packed-bed reactor coupled with a countercurrent heat exchanger in which the cold reactant feed is brought to reaction temperature.

Multifunctional reactors are being developed [508] with the goal of improving operation conditions which are not necessarily optimally determined in standard fixed-bed reactor configurations.

The following industrial processes are performed in various types of fixed-bed reactors:

i) "deep-bed" adiabatic system:
   – Isomerization of $C_4 - C_6$ alkanes or of light gasoline at 620 – 770 K, 20 – 40 bar on Pt-alumina (HCI activated) or on Pt-H-mordenite.

- Catalytic reforming of heavy gasoline using a cascade of single bed reactors at 700 – 820 K, 20 – 25 bar on K-promoted Cr_2O_3-Al_2O_3 catalyst.
- Hydrocracking of vacuum gas oil at 670 – 770 K, 20 – 40 bar, using single or two stage processes on Ni-MoO_3-Y-zeolite-alumina and Pt-mordenite-alumina, respectively.

ii) "multi-bed" adiabatic system:
- Ammonia synthesis at 670 – 770 K, 200 – 300 bar on K-, Mg-, Al-promoted iron catalysts.
- Oxidation of SO_2 in the sulfuric acid production at 720 – 770 K, atmospheric pressure on K_2SO_4-V_2O_5 catalysts. Reactor with externally located heat exchangers are in operation.

iii) "radial flow" system:
- Water gas shift (HTS) at 620 – 670 K, 25 – 50 bar on Cr_2O_3-Fe_2O_3 catalysts.

iv) "shallow-bed" system:
- Methanol dehydrogenation to formaldehyde at 870 K, atmospheric pressure on metallic Ag (granulate).
- Ammonia oxidation to NO_x at 1170 K atmospheric pressure on Pt/Rh-grids.

v) "quench" system:
- Methanol synthesis at 490 – 520 K, 50 – 100 bar on Cu-ZnO-Al_2O_3 catalysts.

vi) "multi-tube" system:
- Methanol synthesis at 490 – 520 K, 50 – 100 bar on Cu-ZnO-Al_2O_3 catalysts.
- Oxidation of ethylene to ethylene oxide at 470 – 520 K, atmospheric pressure on Ag-α-alumina.
- Oxidation of *o*-xylene to phthalic anhydride at 640 – 680 K, at atmospheric pressure on V_2O_5-TiO_2 catalysts.
- Hydrogenation of benzene to cyclohexane at 470 – 520 K, 35 bar on Ni-SiO_2 catalysts.
- Dehydrogenation of ethylbenzene to styrene at 770 – 870 K, atmospheric or reduced pressure on promoted (K, Ce, Mo) Fe-oxide.

Fluidized Bed Reactors [509–512].
Fluidized-bed reactors are preferred over fixed-bed reactors if rapid catalyst deactivation occurs or operation in the explosive regime is required. In this type of reactor, an initially stationary bed of catalyst is brought to a fluidized-state by an upward stream of gas or liquid when the volume flow rate of the fluid exceeds a certain limiting value, the minimum fluidization volume flow rate. The catalyst particles are held suspended in the fluid stream at this or higher flow rates. The pressure drop of fluid passing through the fluidized bed is equal to the difference between the weight of the solid catalyst particles and the buoyancy divided by the cross-sectional area of the bed. Major advantages of fluidized-bed reactors are excellent gas – solid contact, good gas – solid heat and mass transfer, and high bed-wall heat transfer coefficients.

The gas distribution in the fluidized bed is performed industrially by, for example, perforated plates, nozzles, or bubble caps which are mounted at the reactor bottom.

Figure 30. Schematic representation of two forms of gas – solid fluidized beds under turbulent flow conditions

Depending on the volume flow rate of the fluid different types of fluidized beds form. Fluidization with a liquid feed leads to a uniform expansion of the bed. In contrast, solid-free bubbles form when fluidization is carried out in a gas stream. These bubbles move upwards and tend to coalesce to larger bubbles as they reach increasing heights in the bed. At high gas volume flow rates, solid particles are carried out of the bed. To maintain steady-state operation of such a turbulent fluidized bed, the solid catalyst particles entrained in the fluidizing gas must be collected and transported back to the reactor bed. This can be achieved most easily with an integrated cyclone, as schematically shown in Figure 30 A. A circulating fluidized bed is finally formed at still higher gas volume rates. An efficient external

recycle system, as shown in Figure 30 B, is required for such operating conditions because of the high solids entrainment.

Catalytic cracking is carried out in fluidized-bed reactors because the solid acid catalysts are rapidly deactivated by coke deposition. The catalyst must therefore continuously be discharged from the reactor and regenerated in an air-fluidized regenerator bed where the coke is burned off. The regenerated catalyst is then returned to the fluidized-bed reactor. The heat of combustion of the coke can be used for preheating of the reactant feed.

The main advantages of *fluidized-bed* reactors are:

- Uniform temperature distribution (due to intensive solid mixing),
- large solid-gas exchange area and
- high heat-transfer coefficient between bed and immersed heating or cooling surfaces.

However, these reactors have also some disadvantages, e.g.:

- expensive catalyst separation and purification of reaction products (installation of cyclones and filters),
- undesired bypass of reactants due to bubble development,
- catalyst attrition and
- erosion of internals resulting from high solids velocities.

Fluidized-bed reactors found very broad application in the petroleum refining and production of chemicals, for example:

- Catalytic cracking of vacuum gas oil to gasoline at 720 – 820 K on alumosilicates containing ultrastable Y-zeolites.
- Fischer – Tropsch synthesis (Synthol process) from CO und H_2 at 620 – 670 K and 15 – 30 bar on promoted Fe-oxide catalysts.
- Ammoxidation of propylene to acrylonitrile (SOHIO-process) at 670 – 770 K, 1 – 2 bar on promoted Bi-MoO_x catalysts.
- Oxidation of naphthalene or *o*-xylene to phtalic anhydride at 620 – 650 K, at atmospheric pressure on V_2O_5–SiO_2 catalysts.

A special type of the fluidized-bed reactor is the so-called "riser reactor". This reactor consists of a vertical tube in which the reaction takes place in the presence of the entrained catalyst. Catalyst coming from the riser tube is collected in the vessel, before passing through the stripper to the regenerator (fluidized-bed type). The "riser reactor" is mainly used in the catalytic cracking of heavy oils on highly active zeolitic catalysts.

The *moving-bed* reactor [509] operates with spherical catalyst particles larger (2 – 6 mm) than those used in the fluid-bed system. In the standard arrangement, catalyst particles are moving slowly through the agitated bed. Catalyst reaching the reactor top is transported into the regenerator. Using mechanical or pneumatic conveyer the regenerated catalyst is returning to the bottom of the reactor.

The main advantage of the moving-bed reactor is a lower catalyst attrition than in the fluidized-bed system. The disadvantage is a poor heat transfer and therefore this reactor is not suitable for exothermic reactions.

The moving-bed reactor found application mainly in petroleum cracking.

Slurry Reactors [513]. The aim of slurry reactors is intimate contact between a gas phase component (which is to be dissolved in a liquid-phase component) and a finely dispersed solid catalyst (three-phase reactors). The particle size of the solid catalyst is kept sufficiently small ($< 200\,\mu m$) that it remains suspended by the turbulence of the liquid in the slurry reactor. This is in contrast to three-phase fluidized-bed reactors, in which an upward liquid flow is required to suspend the larger catalyst particles.

On the basis of the contacting pattern of the phases and the mechanical devices that achieve contact and the mass transfer, nine types of slurry reactors can be distinguished [513]:

1) Slurry bubble column
2) Countercurrent column
3) Cocurrent upflow
4) Cocurrent downflow
5) Stirred vessel
6) Draft-tube reactor
7) Tray column
8) Rotating-disk or multiagitator column
9) Three-phase spray column

Slurry reactors are industrially applied for a multitude of processes [514], many of which are heterogeneously catalyzed processes for hydrogenation of edible oils. A new development is

the continuous Fischer – Tropsch slurry synthesis process of SASOL in South Africa [515].

Three-phase reactors are classified as fixed-bed or suspension reactors depending on the catalyst arrangement and shape:

Fixed-bed reactors operate either in the "trickle-bed" or in the "bubble-flow" mode [513]. In the first case, liquid reactants or reactants dissolved in a solvent are flowing downward through the catalyst bed and the gaseous reactants are conducted in the countercurrent or concurrent direction.

In the "bubble-flow" reactors, liquid and gaseous reactants are fed into the bottom of the column and are flowing upward through the catalyst fixed-bed.

The "trickle-bed" arrangement has some advantages such as:

- Fast diffusion of gases through the liquid film to the catalyst surface,
- lower back-mixing,
- no problems with catalyst separation,
- selective removal of catalytic poison in the entrance zone of the bed and
- simple catalyst regeneration.

Drawbacks of trickle-bed reactors are:

- Poor heat transfer,
- partial utilization of the catalyst in case of the incomplete wetting and
- possibility of so-called "brooks" formation.

The successful performance of the trickle-phase reactors depends on the suitable diameter/length ratio, catalyst shape and size, and the liquid flow distribution through the catalyst bed. The catalyst particle size is limited by the allowed pressure drop. Larger sizes (6 – 10 mm diameter) are therefore preferred, which, however, can bring diffusion problems.

The "bubble flow" version is favored in particular for reactions with a low space velocity. A good heat transfer and no problems with an incomplete catalyst wetting are the main advantages of the "bubble flow" reactors.

Both types of the three-phase reactors have found numerous industrial applications, e.g.:

- Hydrotreating of petroleum fractions at 570 – 620 K, 30 – 60 bar on Ni-MoO_3-Al_2O_3 catalysts.
- Hydrocracking of high boiling distillates at 570 – 670 K, 200 – 220 bar on Ni-MoO_3-Y-zeolite-alumina catalysts.
- Selective hydogenation of C_4-fractions (removal of dienes and alkines) at 300 – 325 K, 5 – 20 bar on Pd-Al_2O_3 catalysts.
- Hydrogenation of aliphatic carbonyl compounds to alcohols at 370 – 420 K, 30 bar on CuO-Cr_2O_3 catalysts.

Suspension reactors [513], [514] are operated successfully in the chemical industry because of their good heat transfer, temperature control, catalyst utilization, and simple design.

Because of the small catalyst particle size, there are no problems with internal diffusion. *Suspension reactors* operate either in the discontinuous or in the continuos mode.

One serious disadvantage is the difficult catalyst separation, especially if fine particles have to be removed from the viscous liquid.

Currently in use are two types of suspension reactors: "stirred vessels" and "three-phase bubble columns".

In the case of "stirred vessels" the catalyst particles (mainly below 200 μ) are suspended in the liquid reactant or solutions of reactants, whereas gaseous reactants are introduced at the bottom of the vessel through perforated tubes, plates or nozzles. The vessels are equipped with different types of stirrers or turbines keeping the catalyst suspended. Cooling and heating coils as well as the gas recycle system belong to the standard equipment. "Stirred vessels" operate mostly discontinously. However, if continuous operation is favored, then "stirred vessels" are arranged in a cascade to complete the required conversion.

The "bubble column" represents mainly continuously operating three-phase reactors. The gas is introduced at the bottom of the column through nozzles, perforated plates or tubes. In the standard arrangement the liquid reactant flows in the cocurrent direction with the gas. In some cases stirrers are installed to keep powdered catalysts in the suspension.

The gaseous reactants can be recycled by an external loop or by an internal system, such as Ventury jet tube. This equipment is driven by a recycle of the slurry using a simple pump. The Ventury tube is sucking the gas from the free board above the reactor back into the slurry. Heat exchangers can be installed in the loop in both cases.

The main advantages of "bubble columns" are simple and low priced construction, good heat transfer, and temperature control.

Suspension reactors are used predominantly for fat and oil hydrogenation 420 – 470 K, at 5 – 15 bar using various Ni-kieselguhr catalysts.

Also, hydrogenolysis of fatty acid methylesters to fatty alcohols is performed in suspension reactors at 450 – 490 K, 200 – 300 bar on promoted copper chromites ($CuO–Cr_2O_3$).

Further applications are: syntheses of acetaldehyde and of vinylacetate according to the Wacker process.

8.1.4. Special Reactor Types and Processes

Microreactors [516–518]. *Microreactors* (→ Microreators) are used for laboratory testing of catalysts and for fast-throughput techniques, as mentioned in Section 8.1. In addition, microreactor technology can also be applied in synthetic chemistry. A microreactor can be defined as a series of interconnecting channels having diameters between 10 and 300 μm which are formed in a planar surface in which small quantities of reagents are manipulated. Among the advantages of microreactors over conventional catalytic reactors are high heat-transfer coefficients, increased surface to volume ratios of 10 000 to 50 000 $m^2\ m^{-3}$, as opposed to 1000 $m^2\ m^{-3}$ for conventional catalytic laboratory reactors, shorter mixing times, and localized control of concentration gradients. The small scales reduce exposure to toxic or hazardous materials, and the enclosed nature of the microreactors permits greater ease of containment in the event of a runaway reaction. Furthermore, the rapid heat transfer from the area of reaction is fast enough to prevent explosion even when reactions are carried out beyond the explosion limit [518].

Despite their small size, microreactors can be used for synthetic chemistry [519], since as few as 1000 microreactors operating continuously could produce 1 kg of product per day. The first chemical synthesizers are already commercially available. Further developments are still required to make microreactors mature for industrial application, although their use in the production of speciality chemicals and pharmaceuticals seems to be feasible.

Unsteady-State Reactor Operation [520]. Forced unsteady-state reactor operation has been applied to continuous catalytic processes in fixed and f1uidized-bed reactors. This operating mode can lead to improved reactor performance. Nonlinearity of chemical reaction rates and complexity of reaction systems are responsible for conversion or selectivity improvements under forced unsteady-state conditions [521].

An unsteady-state in a fixed-bed reactor can be created by oscillations in the inlet composition or temperature (control function) such as schematically shown in Figure 31. The most widely applied technique in a fixed-bed reactor is periodic flow reversal. Examples of this operation mode in industrial applications are SO_2-oxidation, NO_x-reduction by NH_3, and oxidation of volatile organic compounds (VOC). In fluidized-beds for exothermic reactions, favorable unsteady-state conditions of the catalyst can be achieved by catalyst circulation inside the reactor. The unsteady-state operation in the fluidized-bed is applied for example for the partial oxidation of *n*-butane to maleic anhydride on vanadyl pyrophospate catalysts developed by DuPont. In the first step, *n*-butane diluted with an inert gas is contacted in the riser reactor (residence time 10 – 30 sec) with spherical catalyst particles (100 μ). The partial oxidation of n-butane proceeds on account of the lattice oxygen in the surface layer of vanadyl pyrophosphate. In the second step, the partially reduced catalyst is transported into the fluidized-bed reactor where the catalyst reoxidation takes place. The obtained selectivity was about 10 % higher than that in the multitubular fixed-bed reactor, operating under steady-state conditions. A further group of forced unsteady-state processes uses the combination of a chemical reaction with the separation of products (chromatographic reactor). Systems applied till today operating on the principle of chromatographic columns are filled with a catalyst possessing suitable adsorption properties, such as $Pt-Al_2O_3$. Pulses of reactant are periodically injected into this reactor which is purged by carrier gas during periods between the pulses. This operation can provide a higher conversion for reversible reactions if one of the reaction products is adsorbed on the

catalyst more strongly than the other one. The feasibility of this principle was tested in the dehydrogenation of cyclohexane to benzene on pilot scale.

Figure 31. Stepwise variation of inlet parameters to create unsteady state conditions

Membrane Reactors [522–524]. In membrane reactors (→ Membrane Reactors) catalytic conversion is coupled with a separation effect provided by the integrated membrane. High conversions can be achieved for equilibrium-restricted reactions when one of the reaction products can be removed from the reaction mixture by diffusion through a permselective membrane. Hydrocarbon dehydrogenation reactions are the best example for this application. In addition, catalytic membrane reactors have been proposed for improved control of the selectivity of some catalytic reactions. For example, controlled introduction of a reactant into the reactor by selective or preferential permeation may limit possible secondary reactions of the target product.

Two types of membranes can be distinguished: dense membranes and porous membranes. Dense metallic membranes consist of thin metal foils. Palladium and palladium alloys (PdAg, PdRu) are specific for hydrogen permeation. Dense oxide membranes are usually solid electrolytes such as ZrO_2 or CeO_2, which are permeable for O_2 [524]. Porous membranes are typically made of oxides, although carbon membranes have also been used [525]. Ceramic membranes consist of several layers of material with progressively decreasing pore size. The top layer with the smallest pore size controls the separation. Most of these membranes are produced by sol – gel techniques. Intrinsic catalytic properties can be introduced into these membranes, which can be produced as cylindrical tubes forming the basis for tubular reactors. Zeolite membranes can also be prepared, and the structure of the zeolite should permit high selectivity in separation processes.

Despite the potential of membrane reactors, their development is still not mature for industrial application.

Reactive Distillation [526–528]. In reactive distillation (→ Reactive Distillation) fractional distillation and chemical reaction are performed simultaneously, e.g., for a reaction of the type

$$A + B \longrightarrow C + D$$

in which at least one of the products has a volatility which is different form those of the other compounds. The most attractive features of reactive distillation are:

1) The separation of at least one of the products by distillation drives reactions to completion which are otherwise equilibrium-limited.
2) Reactions in which high concentrations of a product or one of the reactants lead to undesired side reaction, can be carried out.

Despite these advantages, several chemical and physical limitations exist in practice for its use in chemical processes, so that reactive distillation has found application for only a few important reactions.

Industrially important processes are various etherifications, esterifications, alkylations or isomerizations.

IFP, Mobil, Neste Oy, Snamprogetti, Texaco, and UOP are providing licenses for plants to produce t-butyl- or t-amyl ethers from corresponding olefins and methanol or ethanol using strong acidic resins as solid catalyst.

Reactions under Supercritical Conditions [529–532]. Only in the last decade have reactions under supercritical conditions gained importance in chemical technology because of the relatively high pressures and the rigorous demands on the equipment usually required when working in supercritical fluids. The major advantage of these media as solvents in catalytic reactions is the fact that carbon dioxide and water can be used as environmentally benign solvents. When in their supercritical state, these nontoxic compounds are good solvents for many organic compounds. A multicomponent system under supercritical conditions may behave like a

single gaslike phase with advantageous physical properties. Under reaction conditions this leads to [529]:

1) Higher reactant concentrations
2) Elimination of contact problems and diffusion limitations in multiphase reaction systems
3) Easier separations and downstream processing
4) In situ extraction of coke precursors
5) Strongly pressure and temperature dependent solvent properties near the critical point
6) Higher diffusivities than in liquid solvents
7) Better heat transfer than in gases
8) Use of clustering to alter selectivities

Hence, supercritical fluids offer strategies for more economical and environmentally benign process design, mainly because of enhanced reaction rates, prolongation of catalyst lifetime, and simplification of downstream processing.

8.2. Filling Fixed-Bed Reactors

In filling the reactor, catalyst distribution and particle size must be uniform to avoid channeling, leading to poor heat transfer and impairment of catalyst performance. In a *multitube reactor*, the pressure drop must be the same in each tube so that the gas flow is distributed uniformly over the tubes. Small changes in the packing density in the tubes can cause uneven heat transfer and, in the case of highly exothermic reactions, hot spots and selectivity loss. For these reasons multitube reactors are filled by special equipment that charges each tube with the same amount of catalyst at a definite rate. After filling, the tubes are checked for pressure drop, and if necessary, the charge is adjusted. Satisfactory heat transfer and uniform gas flow can only be accomplished if the reactor tube diameter is approximately 8 – 10 times, and the reactor length 50 – 200 times, as large as the diameter of the catalyst particle. For reactions occurring at atmospheric pressure, the catalyst size should not exceed 1 cm to avoid channeling and to ensure full utilization of catalyst activity.

Pyrophoric catalysts are charged from special containers filled with inert gas and provided with an adapter for displacing air from the reactor or reactor tubes. Corresponding safety measures are also taken on discharging air-sensitive catalysts from reactors. However, passivated catalysts and catalysts embedded in, or coated with, protective, high-binding material (e.g., hardened edible oil for hydrogenation catalysts) can be handled without precautionary measures.

8.3. Reactor Start-Up

During the initial days of operation of many heterogeneous catalytic processes, especially in selective oxidation reactions, a fresh catalyst undergoes minor chemical and physical changes (oxidation, reduction, sintering, etc.) before it reaches a steady state. During this time the reactor is operated according to a prescribed program at reduced throughput to avoid damage to the catalyst by heat evolution in case unexpectedly high activity should develop in the start-up period. When using nickel-containing catalysts below 420 K, carbon monoxide must be completely excluded from the reactants to prevent the formation of highly toxic nickel carbonyl and the destruction of the catalyst.

8.4. Diffusion, Mass and Heat Transfer Effects [63], [533], [534]

Heterogeneous catalytic reactions take place on the external and internal surfaces (pores) of the catalyst. *External and internal concentration* and *temperature gradients* can build up in the fluid (gas or liquid) boundary layer around the catalyst particles and inside the pores if the mass and heat transfer between the bulk of the fluid and the active surfaces is not sufficiently fast. Such gradients tend to exist (1) in fixed-bed reactors charged with large, porous catalysts; (2) in operation at low-mass flow velocities (mass flow rate per unit cross-sectional area); or (3) in the case of highly exothermic reactions. On the other hand, gradient effects usually are absent when nonporous catalysts are used in fluidized-bed reactors or in fixed-bed reactors at high mass velocities.

Because such internal and external gradients can substantially reduce the activity and the selectivity of the catalyst, conditions have been delineated under which their adverse effects can

be minimized [63], [533], [534]. By carefully matching operating conditions, catalyst, and reactor, optimum catalyst performance can be ensured.

Mass and heat transfer in heterogeneous catalytic reactions occurs in two ways. *External transport* to the external surface involves diffusion through the more or less stationary hydrodynamic boundary layer that surrounds the catalyst particle. The thickness of this layer depends on the characteristics of the fluid and its flow rate past the particle, and affects the rate of mass and heat transfer. The *internal transport* to the stationary fluid in the pores of catalyst particle is controlled by diffusion alone.

Depending on the relative rates of the transport processes and of the catalytic reaction, three or four types of regimes can be distinguished. In the *kinetic regime* the rates of external and internal mass transport are much higher than the rate of the chemical reaction. Therefore, concentration and temperature gradients between the fluid and the center of a catalyst particle are negligible, and the catalyst is fully utilized.

In the *internal diffusion regime*, mass transport in the catalyst pores is about as fast as, or slower than, the chemical reaction. In this case there are considerable concentration gradients along the length of the pores, the effectiveness of the catalyst is impaired, and the apparent energy of activation is lower than that observed in the kinetic regime.

At a still lower ratio of rates of transport and conversion, there is an *intermediate regime* in which the reaction takes place only on the external surface of the catalyst particles while the internal surface of the pore is inactive. Because of the limited heat transfer in this regime, exothermic reactions can overheat the catalyst, resulting in a higher activity than that corresponding to the temperature of the fluid.

Finally, on further decrease of the ratio of the rates of transport and conversion (e.g., by raising the temperature of the fluid), the *external mass transfer regime* is reached in which the reaction rate is controlled by mass transfer, and the concentration of the reactants at the surface of the catalyst particles drops. Raising the reactor temperature in this regime has little effect on the reaction rate, and the apparent activation energy drops.

8.4.1. Effectiveness Factor [63], [533], [534]

The *effectiveness factor* η is the ratio of the actual reaction rate observed on a porous catalyst particle to the rate that would be obtained if the inside of the particle were exposed to the temperature and reactant concentrations of the fluid. Mathematical analysis [63], [535–544] of mass transfer in porous particles of different shapes has shown that effectiveness is a function of a dimensionless quantity, called the *Thiele diffusion modulus* φ [535]: for a sphere of radius R and for a plate sealed on one side and on the edges the thickness of which is L, φ is defined by the following equations:

$$\text{sphere}: \varphi_{\mathrm{s}} = R\left(\frac{k_{\mathrm{v}}\, c_{\mathrm{s}}^{m-1}}{D_{\mathrm{eff}}}\right)^{1/2} \tag{60}$$

$$\text{plate}: \varphi_{\mathrm{L}} = L\left(\frac{k_{\mathrm{v}}\, c_{\mathrm{s}}^{m-1}}{D_{\mathrm{eff}}}\right)^{1/2}$$

where k_{v} is the reaction rate constant per unit of gross catalyst volume, c_{s} is the concentration on the surface, m is the reaction order, and D_{eff} the effective diffusion coefficient, given by

$$D_{\mathrm{eff}} = D\frac{\Theta}{\tau} \tag{61}$$

where D is the diffusion coefficient for a pair of fluids, Θ the void fraction of the porous mass, and τ a factor allowing for tortuosity and varying cross-sections of the pores.

For first-order reactions ($m = 1$), the effectiveness factors are as follows (tan is hyperbolic tangent):

$$\text{sphere}: \eta = \frac{3}{\varphi}\left(\frac{1}{\tan\varphi_{\mathrm{s}}} - \frac{1}{\varphi_{\mathrm{s}}}\right) \tag{62}$$

$$\text{plate}: \eta = \frac{\tan\varphi_{\mathrm{L}}}{\varphi_{\mathrm{L}}}$$

Correlation between the effectiveness factor and the Thiele modulus for nonexothermic reactions is shown in Figure 32 [540]. The effectiveness factor is ca. unity for $\varphi < 1$ and inversely proportional to φ for $\varphi > 3$.

If the intrinsic velocity constant k_{v} (Eqs. 61 and 62) cannot be determined directly, another dimensionless modulus Φ has been derived [538–540]. For first-order reactions occurring in a sphere, it is defined by

$$\Phi \equiv \varphi^2 \eta = \left(\frac{R^2}{D_{\text{eff}} V_{\text{c}} C_{\text{s}}}\right)\left(\frac{\text{d}n}{\text{d}t}\right) \tag{63}$$

where dn/dt is the conversion rate in moles per second of the reactant in the catalyst volume V_{c}. The effectiveness factor as a function of Φ is shown in Figure 33 for a moderate energy of activation ($E = 10\,RT$; first-order reaction in a spherical particle) and variable enthalpy change ΔH (λ is the thermal conductivity of the catalyst). For exothermic reactions ($\beta > 0$), the effectiveness factor goes through a maximum value exceeding unity because of the interaction of two opposing effects. Poor mass transfer lowers the efficiency of the catalyst, whereas insufficient heat transfer raises catalyst temperature and reaction rate.

Figure 32. Effectiveness factor φ as a function of the Thiele modulus φ_{s} or σ_{L}

8.4.2. Effects on Selectivity [63], [533], [534]

The effect of mass and heat transport processes on the selectivity of reactions yielding more than one product depends on the *selectivity type*. In a type **I** reaction at low-effectiveness factors, the observed selectivity factor changes from k_1/k_2 to $(k_1\ D_{\text{Aeff}}\ k_2^{-1}\ D_{\text{Beff}}^{-1})^{1/2}$, provided the order of the two reactions (A → X and B → Y) is the same. If, as usual, the ratio of the effective diffusivities is smaller than k_1/k_2, the selectivity will drop at low effectiveness factors. However, if the diffusivity ratio is high, the selectivity can increase in a porous catalyst. This is the situation in the so-called shape selective zeolites [63]. If the reaction orders are different, the reaction with the lower order is favored in the porous catalyst at low η values.

In reaction type **II**, the effectiveness factor has no influence on the selectivity if the orders of the two reactions are equal. Otherwise, the effect of different orders is the same as in type **II** reactions [534], [545].

For an isothermal first-order reaction of type **III** occurring at low effectiveness factor on a porous plate, the observed selectivity is approximately the square root of the intrinsic rate constant ratio k_1/k_2 [546]. Figure 34 shows comparative conversions of A to X for type **III** at effectiveness factors $\eta = 1$ and $\eta < 0.3$, for $k_1/k_2 = 4$; the maximum yield and selectivity both drop by ca. 50 % at the low effectiveness factor [546].

Figure 34. Effect of the effectiveness factor on catalyst selectivity
∗ Reproduced with permission [546]

Temperature gradients caused by exothermic reactions favor reactions with the higher apparent *energies of activation*. Because such undesired side reactions as decomposition and oxidative degradation generally have high energies of activation, large catalysts having narrow pore structure can have an unfavorable effect on the selectivity and product yield.

In the regime of external mass transfer, resistance of the boundary layer to *diffusion* has similar effects on the selectivity of parallel and consecutive reactions as does diffusion in pores.

8.4.3. Catalysts and Transfer Processes

Industrial processes that occur in the kinetic regime include reactions conducted in fluidized-bed reactors using catalysts 0.05 – 0.25 mm in size [63], [534]. Because diffusion coefficients in liquids are smaller by several orders of magnitude than those in the gaseous phase, liquid-phase operation in the kinetic regime requires a finely powdered catalyst.

Because the resistance to flow of catalysts increases steeply with decreasing size, use of catalysts smaller than 2 – 3 mm in fixed-bed reactors is restricted to radial flow, slurry, and riser reactions. Ring-shaped and tableted catalysts show relatively favorable pressure drop and diffusion characteristics.

In various partial oxidation processes (e.g., naphthalene or *o*-xylene to phthalic anhydride), good results have been obtained with so-called *egg shell catalysts* in which the active catalyst mass is applied in a thin layer of a few tenths of a millimeter to the external surface of an inert, nonporous support.

In the regime of *internal diffusion*, it is often advantageous to use catalysts with a bimodal pore system in which micropores (< 2 nm) are connected by macropores (> 50 nm) to the external surface of the catalyst particle. The micropores provide the needed high surface, whereas the macropores facilitate mass transport to and from the micropores. Such catalysts are especially suitable for operation at process pressures below 3 MPa (30 bar). At these pressures mass transport into pores smaller than 100 – 1000 nm occurs increasingly through *Knudsen diffusion* involving molecular collisions with the pore wall rather than between molecules [63], [534].

In fast processes occurring in the regime of *external mass transfer*, the overall conversion rate is independent of the porosity of the catalyst and is essentially proportional to its external surface area [541]. Examples of such reactions are oxidation of ammonia to nitric acid and ammoxidation of methane to hydrogen cyanide carried out at 1070 – 1270 K on stacks of fine mesh Pt – Rh gauze.

9. Catalyst Deactivation and Regeneration

9.1. Different Types of Deactivation

As has been observed in the laboratory and in industrial application, heterogeneous catalysts are deactivated during time on stream. For example, in fluid-bed catalytic cracking and propene ammoxidation the catalyst life is limited to a few seconds or minutes, while in other reactions, such as NH_3 and CO oxidation the catalyst remains active for several years. Not only loss of activity but also a decrease in selectivity is usually caused by catalyst deactivation [410], [547], [548].

The activity loss can be compensated within certain limits by increasing the reaction temperature. However, if such compensation is not efficient enough, the catalyst must be regenerated or replaced.

The main reasons for catalyst deactivation are:

1) Poisoning
2) Fouling
3) Thermal degradation
4) Volatilization of active components

Some types of catalyst deactivation are reversible, e.g., catalyst fouling and some special types of poisoning. Other types of deactivation are mostly irreversible [410], [547], [549].

Catalyst Poisoning. The blocking of active sites by certain elements or compounds accompanied by chemisorption or formation of surface complexes are the main causes of catalyst deactivation [410], [547], [549]. If the chemisorption is weak, reactivation may occur; if it is strong, deactivation results. Chemical species often considered as poisons can be divided in five classes:

1) Group 15 and 16 elements such as As, P, S, Se and Te
2) Metals and ions, e.g., Pb, Hg, Sb, Cd
3) Molecules with free electron pairs that are strongly chemisorbed, e.g., CO, HCN, NO
4) NH_3, H_2O and organic bases, e.g., aliphatic or aromatic amines, pyridine, and quinoline
5) Various compounds which can react with different active sites, e.g., NO, SO_2, SO_3, CO_2.

Elements of the class (1) and their compounds, for example, H_2S, mercaptans, PH_3, and AsH_3, are very strong poisons for metallic catalysts, especially for those containing Ni, Co, Cu, Fe, and noble metals [410], [547], [549].

Elements of the class (2) can form alloys with active metals and deactivate various systems in this way [410], [550].

CO is chemisorbed strongly on Ni or Co and blocks active sites. Below 450 K and at elevated pressure the formation of volatile metal carbonyls is possible [410], [547], and catalyst activity is strongly reduced.

Ammonia, amines, alcohols, and water are well known poisons for acidic catalysts, especially for those based on zeolites [410], [551].

Catalysts or carriers containing alkali metals are sensitive to CO_2, SO_2, and SO_3.

Catalyst Fouling. Because most catalysts and supports are porous, blockage of pores, especially of micropores, by polymeric compounds is a frequent cause of catalyst deactivation. At elevated temperatures (>770 K) such polymers are transformed to black carbonaceous materials generally called *coke* [410], [552]. Catalysts possessing acidic or hydrogenating – dehydrogenating functions are especially sensitive to coking.

There are different types of coke, such as C_α, C_β, carbidic or graphitic coke, and whisker carbon [410]. C_α is atomic carbon formed as a result of hydrocarbon cracking on nickel surfaces above 870 K. C_α carbon can be transformed at higher temperatures to polymeric carbon (C_β) which has a strongly deactivating effect. C_α carbon can also dissolve in metals and forms metal carbides, and it may precipitate at grain boundaries. Metal-dissolved carbon may also initiate the growth of carbon whiskers, which can bear metal particles at their tops.

Coke formation can be minimized, for example, in methane steam reforming by sufficiently high steam/methane ratio or/and by the alkalization of the carrier.

Thermal Degradation. One type of thermal degradation is the agglomeration of small metal crystallites below the melting point, called *sintering* [410]. The rate of sintering increases with increasing temperature. The presence of steam in the feed can accelerate the sintering of metal crystallites.

Another type of thermal degradation are solid-solid reactions occurring especially at higher temperatures (above 970 K). Examples are reactions between metals, such as Cu, Ni, Co, and alumina carriers which result in the formation of *inactive* metal aluminates [410], [553].

Also, phase changes belong to the category of thermal degradations. A prominent example is the reduction of the surface area of alumina from $250\,m^2\,g^{-1}$ (γ phase) to $1-2\,m^2\,g^{-1}$ (α phase) by thermal treatment between 870 and 1270 K.

Alternating oxidation and reduction of the system, as well as temperature fluctuations, are often accompanied by activity losses and can cause mechanical strain in catalyst pellets. Therefore, mechanical strength of catalyst particles has major industrial importance.

Volatization of Active Components. Some catalytic systems containing P_2O_5, MoO_3, Bi_2O_3, etc. lose their activity on heating close to the sublimation point. Cu, Ni, Fe and noble metals can escape from catalysts after conversion to volatile chlorides if traces of chlorine are present in the feed.

9.2. Catalyst Regeneration

The regeneration of metallic catalysts poisoned by Group 16 elements is generally rather difficult. For example, oxidation of sulfur-poisoned metallic catalysts converts metal sulfides to SO_3, which desorbs from metals. However, if the catalyst or carrier contains Al_2O_3, ZnO, MgO then SO_3 forms the corresponding sulfates. When the catalyst is subsequently brought on-line under reducing conditions, then H_2S is formed from sulfates and the catalyst will be repoisoned [410], [554].

Therefore it is necessary to remove poisons from the feed as completely as possible. Further prevention is the installation of a guard-bed containing effective poison adsorbents in front of the reactor.

Ni catalysts poisoned with CO or HCN can be regenerated by H_2 treatment at temperatures that allow formation of methane and NH_3, respectively.

The original activity of acidic catalysts poisoned partially by H_2O, alcohols, NH_3, and amines can be restored by thermal treatment at sufficiently high temperatures.

From the industrial point of view, the regeneration of coked catalysts is very important. The removal of coke depends on its structure and on the catalyst composition. Alkali metals, especially potassium, accelerate coke gasification. Oxidation is the fastest gasification reaction, but it is highly exothermic [410], [555]. To maintain the temperature within allowed limits, mixtures of O_2, steam, and N_2 are mainly used to remove the coke.

Catalysts deactivated by thermal degradation are very difficult to regenerate. Certain $Pt-Al_2O_3$ catalysts, deactivated as a result of thermal Pt sintering, can be partly regenerated by chlorine treatment at elevated temperatures, which makes Pt redistribution possible.

9.3. Catalyst Reworking and Disposal

The leaching of precious metals from spent catalysts is widely practiced. Producers of noble metal catalysts, such as Engelhard Corp., Johnson Matthey, and Degussa have plants for this purpose. Yields of recovered precious metals are 90 – 98 % depending on the original metal content and on the nature of the support used.

Besides precious metals, Ni from spent Ni – kieselguhr catalysts used in fat and oil hydrogenations are reworked to a large extent. Before Ni leaching, fats must be removed.

Hydrotreating catalysts containing Mo, Ni or Co are also reworked. Before leaching of the metals, coke and sulfur are removed by roasting [410], [547].

In various cases, however, problems arise when the price of recovered components does not cover the costs of catalyst reworking. The final alternative is the disposal of the spent catalyst. In general, catalysts containing Al, Si, Fe can be disposed of without any special precautions or can be used in construction materials. However, if such catalysts contain Ni or V accumulated during their use, then removal of these elements below legislative limits is necessary [410].

Spent Cu- and Cr-containing catalysts are sometimes accepted by metallurgical plants.

Before disposal, spent catalysts containing various contaminants need to be encapsulated to avoid their release into water. Materials used for encapsulation are, e.g., bitumen, cement, wax, and polyethylene [410]. Nevertheless, the disposal of encapsulated catalysts is not only expensive but is becoming increasingly difficult.

1. Definition and Classification

Cationic dyes carry a positive charge in their molecule. The salt-forming counterion is, in most cases, the colorless anion of a low molecular mass inorganic or organic acid. Many of these dyes can be converted into water-insoluble dye bases by addition of alkali. For this reason, they were formerly called *basic dyes*; although still in use today, the term should be abandoned.

The positive charge of cationic dyes may be either localized or delocalized. In (**1**), the positive charge is localized at an ammonium group:

1

In the diazahemicyanine dye **2**, the positive charge is delocalized across the dye cation.

2

As in these examples, the charge-carrying atom is usually nitrogen, but in some dyes this function is adopted by an oxygen, sulfur, or phosphorus atom.

This article gives a short survey on cationic dyes and shows typical representatives of each class of cationic dye. In general, dyes are classified according to their chemical structure in this encyclopedia. For further detail the reader is referred to the following individual keywords:

Anthraquinone Dyes and Intermediates, Azine Dyes, Azo Dyes, Benzoquinone and Naphthoquinone Dyes, Fluorescent Dyes, Methine Dyes and Pigments, Naphthalimide Dyes and Pigments, Nitro and Nitroso Dyes, Optical Brighteners, Phthalocyanines, Triarylmethane and Diarylmethane Dyes.

1.1. Dyes with Delocalized Charge

Cationic dyes with delocalized charge are classified with the *methine dyes*. They may be viewed as vinylogous amidinium salts (**3**) [1]:

3

All of these dyes may be represented by various resonance formulas. They are characterized by a high color strength.

Dyes in which both charged terminal atoms are not part of a heterocyclic ring are called *streptocyanine dyes*. An example is (**4**), which dyes paper in a greenish yellow shade [2]:

4

In the *hemicyanine dyes*, one of the charged terminal atoms is part of a heterocyclic ring, and the other is a nitrogen atom directly linked to the methine chain (**5**):

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a05_369

5

An example of this type is the *enamine dye* (**6**), which confers a yellow color to polyacrylonitrile fibers [3]:

6

Insertion of an aryl residue between the second nitrogen atom and the methine chain leads to the *styryl dyes*, which dye polyacrylonitrile in red and purple shades, e.g., (**7**) [4]:

7

In a special form of this type, the chain may be completely missing. This leads to *zeromethine dyes* such as (**8**) [5], which dye polyacrylonitrile in very lightfast violet and blue shades.

8

If tazhe second charged terminal atom is also part of a heterocyclic ring, the *cyanine dyes* are obtained (**9**).

9

These dyes are used predominantly as photographic spectral sensitizers. Compound (**10**) dyes paper in brilliant pink shades [6]:

10

One or several of the carbon atoms in the chain may be replaced by nitrogen, as is indicated by the prefix "aza." Depending on the number of nitrogen atoms introduced into the chain, one may obtain either *mono-* or *diazadimethine dyes*. *Tri-* and *tetraazamethine* dyes are also known. An example is dye (**11**), which gives polyacrylonitrile fibers a golden yellow tint [7]:

11

Another example is the above-mentioned dye **2**, which dyes polyacrylonitrile in lightfast blue shades [8].

Diphenylmethane and *triphenylmethane dyes* are monomethine dyes with two or three terminal aryl systems; of these at least one but preferably two or three are substituted by a donor group *para* to the methine carbon atom. The most important donor is the amino group. Important dyes belonging to this class include the well-known >malachite green (**12**) [9] and crystal violet (**13**)[10], which are some of the oldest synthetic cationic dyes:

12

13

Introduction of an oxygen bridge into the triphenylmethane dye molecule leads to the *xanthene dyes.* The shade is shifted from blue to red. The restricted rotation of the phenyl residues inhibits radiationless de-excitation and gives rise to very strong fluorescence. Rhodamine B (**14**) is used for dyeing paper [11] and as a laser dye:

14

Azine dyes, which have the general formula (**15**) are ring-closed azadiphenylmethane or indamine dyes. Examples are *phenazine dyes, oxazine dyes,* and *thiazine dyes*.

15

where Y = -O-,-S-, or -NR-
R = hydrogen, alkyl, aryl

The phenazine dye mauveine (**16**), discovered by PERKIN [12], was the first synthetic dye produced on an industrial scale.

mixture with R = H, CH_3

16

Of current importance are the oxazine dye (**17**)[13] and the thiazine dye (**18**) (methylene blue) [14]:

17

18

1.2. Dyes with Localized Charge

In contrast to dyes with delocalized charge, in which the charge is an essential part of the chromophore, in dyes with localized charge the charged atom in most cases is isolated from the chromophore by a nonconjugated group. Therefore, any chromophore can be used, and this chromophore is not or only slightly influenced by the charged atom.

Representatives of cationic dyes with localized charge are found in the following classes of dyes:

1) *Azo Dyes.* The localized charge in cationic azo dyes may reside either in the diazo moiety (formula **19**) [15] or in the coupling component (formula **20**) [16]:

19

20

2) *Anthraquinone dyes* [17]:

21

3) *Phthalocyanine dyes* [18]:

22

where n = 2-8

4) *Perinone dyes* [19]:

23

5) *Naphthalimide dyes* [20]:

24

6) *Quinophthalone dyes* [21]:

25

7) *Neutrocyanine dyes* [22]:

26

8) *Nitro dyes* [23]:

27

2. Applications

Cationic dyes were used initially for dyeing of silk, leather, paper, and cotton mordanted with tannin, as well as for the production of ink and copying paper in the office supplies industry. Their high brilliance and color strength partly compensated for their poor lightfastness on these materials. With the development of synthetic fibers their most suitable substrates were found, and their importance for dyeing textiles increased greatly. Cationic dyes were employed initially for printing of cellulose acetate but gained much greater importance for dyeing of polyacrylonitrile, acid-modified polyester, and polyamide fibers.

2.1. Dyeing of Synthetic Fibers

GLENZ and BECKMANN [24] were the first to investigate color balance and surface potentials in polyacrylonitrile fibers. On the basis of their results, they proposed the following dyeing mechanism: The cationic chromophore is first absorbed by the negatively charged fiber surface and then diffuses from there, at elevated temperature, into the interior of the fiber; there it binds to active acid groups, the number of which is limited and the accessibility of which depends on temperature and fiber constitution. Therefore, the dyeing characteristics of a cationic dye are determined by affinity and diffusibility.

The *affinity* of cationic dyes is enhanced by increasing the size of the molecule and especially by introducing aromatic residues. The phenyl-substituted dye (**28**) is absorbed onto polyacrylonitrile materials at a higher rate than the dye (**11**) [25].

28

Residues which make the substance more hydrophilic, such as carboxyl and hydroxyethyl groups, lower the affinity of cationic dyes for polyacrylonitrile. Therefore, dye (**29**) is absorbed onto polyacrylonitrile materials much more slowly than dye **2** [26].

29

High affinity may, however, lead to problems in leveling because these dyes are bound quickly

and nearly irreversibly to the acid groups of the fiber.

Diffusibility increases with decreasing molecular mass. Dyes with a cation mass of less than 275 migrate well and are suitable for the production of level dyeings, especially in the lighter shades [27].

Cationic dyes are also used to dye polyacrylonitrile fibers during the spinning process either from dimethylformamide solution or in the gel stage subsequent to aqueous spinning processes.

Du Pont started production of polyacrylonitrile fibers in the United States in 1944; ten years later Bayer started production in Western Europe. Total fiber production amounted to 10 000 t in 1950, increased to 129 000 t by 1960, and reached 1 005 000 t in 1970. Production doubled within the next 10 years and reached 2 577 000 t in 1996. Worldwide capacities amount to 3 148 000 t. They are mainly located in Asia (1 584 000 t) and Western Europe (751 000 t). North America, South America, and Eastern Europe (including the former Soviet Union) each have capacities in the range of 230 000 to 300 000 t. The largest producing company of polyacrylonitrile fibers is Enichem/Montefibre in Italy and Spain (320 000 t). Japan has the largest capacity (444 000 t), followed by Germany, Italy, and China with 255 000 to 350 000 t. Acrylic fibers represent 6.5 % of world textile fiber usage.

In Western Europe, the bulk of acrylic fibers is targeted for the clothing industry. As much as two-thirds of the acrylic fiber production is used in this sector, whereas only one-third is used for home furnishings and in technical applications.

2.2. Dyeing of Paper, Leather, and Other Substrates

Cationic dyes exhibit good affinity for negatively charged wood pulp and unbleached pulp grades. Anionic fixing agents improve their wetfastness. Cationic dyes are chosen because of their brilliance and intensity, which makes them especially valuable for recycled paper grades. Their poor lightfastness is not a maior problem because of the low light stability of the substrate itself. They suffer from poor affinity for bleached, lignin-free pulp grades, which are used, for instance, in the manufacture of table cloths and napkins. Therefore, dyes have been developed for this application that bear several cationic charges linked by substantive moieties, such as urea or triazine [28], e.g., **30**.

30

Cationic dyes were the first synthetic organic dyes employed for dyeing leather, initially for dyeing of vegetable tanned leather. Brilliant cationic dyes are used for enhancing the brilliance of the shades obtained with 1/2 metal complex dyes.

Because of their coloring strength, cationic dyes are used in the office supplies industry for the manufacture of ink, typewriter ribbon, and copying paper.

Colorless derivatives of the carbinol bases of cationic dyes are used for the manufacture of carbonless copy paper and for special paper used for thermal printers. Examples of such color formers are the crystal violet derivative **31** [29], which gives a blue color development, and the black-developing fluorane lactone **32** [30] and benzoxazine **33** [31].

31

32

33

Cationic dyes which absorb in the near infrared part of the spectrum are used in optical data storage disks, e.g., **34** [32]:

34

3. Economic Aspects

In assessing the economic importance of cationic dyes, it is not possible to distinguish between dyes bearing localized and delocalized charges. Worldwide, 20 000 t of cationic dyes was used in 1995 to dye polyacrylonitrile. Some additional quantities, which cannot exactly be quantified, are used in China, India, and the former Soviet Union. Dominant regions are Western Europe including Turkey, the United States, Canada, and Mexico. In Japan usage is decreasing. Usage increased most rapidly in developing nations. Market leaders are DyStar, Ciba, BASF, and Yorkshire, who have a total market share of 58 %.

More than one-third of the worldwide tonnage consists of the following dyes: Basic Yellow 28 (Astrazon Golden Yellow GL [*36528-10-6*]: 2200 t, Basic Red 18 (Astrazon Red GTL) [*25198-22-5*], and Basic Red 54 (Maxilon Red 2GL) [*36984-04-6*]: 600 t, Basic Red 46 (Maxilon Red GRL) [*12270-28-9*], [*29508-47-2*]: 1100 t, Basic Blue 41(Maxilon Blue GRL) [*26850-47-5*]: 1000 t, BasicBlue 3 (Basacryl Blue X-5G) [*4444-00-2*]: 300 t, Basic Green 4 (malachite green) [*569-64-2*]: 2000 t. An additional 5000 t of yellow, red, and blue dyes are used in mixturesto yield black shades. Dyes with special coloristic properties such as brilliance, fluorescence, and dye bath stability, make up another 7800 t.

In 1996, 16 000 t of cationic dyes with a total value of DM 210 $\times$ 10^6 were used for dyeing paper worldwide. One-half of this are yellow dyes. The other half is split up as follows: orange: 1000 t, red: 2000 t, blue: 1200 t, violet: 2200 t, green: 1000 t. Market leaders are BASF, Zeneca, and Bayer, who share 72 % of the market. There is no trend for a shift to developing countries.

In 1996, 6500 to 7000 t of color formers were used worldwide, 60 % in the production of carbonless copy paper and 40 % in the production of paper for thermal printers, e.g., in fax machines, tills, and ticket printers. Market leaders are Ciba, Yamada, Yamamoto, and Hilton-Davis, who share 90 % of the market.

1. Cellulose

Hans Krässig and Josef Schurz

Cellulose [9004-34-6] deserves a special position among the industrially used raw materials for two general reasons. First, cellulose belongs to the natural products which, when used carefully, are inexhaustible since it is regularly regenerated by nature in relatively short time periods. As long as we ensure that the primary sources of cellulose, forests and cotton plantations, are not damaged by destructive lumbering or overcropping, we can expect regular and significant natural annual reproduction.

According to reference [8], the annual yield of cellulosic matter resulting from photoinitiated biosynthesis amounts to approximately 1.3×10^9 metric tons. A tree produces an average of 13.7 g of cellulose daily. If they were lined up, the cellulose chain molecules formed each day would result in a string of 2.62×10^{10} km in length, or 175 times the distance between the sun and the earth.

In wood, cellulose is part of an ingeniously constructed fiber-reinforced composite in which long, stiff cellulose chain molecules organized in thin fibrils constitute the plant reticulum material held together and protected by hydrophobic lignin acting as binder and encasement.

To isolate cellulose from wood for industrial applications, the wooden composite must be broken up by so-called pulping processes. In these treatments, other wood constituents, such as lignin and hemicelluloses, are to a large extent degraded and dissolved. Thus far, these byproducts have found only limited use. In most cases, wood pulp manufacturers concentrate the waste pulping liquors to concentrates consisting of ca. 50 % solids. The organic matter is used as fuel to produce steam and electric power, while the inorganic pulping chemicals (soda, magnesium, or ammonium base and sulfur dioxide) are simultaneously recovered. These recovery processes have practically solved the long-standing environmental problems of the wood pulp industry.

Both cellulose and lignin are biologically degradable and, thus, ecologically beneficial. They will decompose in the open. Cellulose products, such as paper or cellulosic textiles, will decompose and eventually form valuable humus. In industrial use, environmental problems are not caused by cellulose or lignin but by the chemicals used in the isolation or in subsequent chemical processing and transformation into cellulose derivatives, films, or fibers. Therefore, the long-term task of modern cellulose research will be the development of novel processes which yield no or only a few ecologically harmful byproducts. If these efforts are successful, cellulose will surely maintain and strengthen its position as a renewable and environmentally beneficial, industrially important raw material competing with synthetically produced polymers.

1.1. Properties

1.1.1. *Molecular Structure*

Cellulose is an isotactic β-1,4-polyacetal of cellobiose (4-*O*- β-D-glucopyranosyl-D-glucose). The actual base unit, the cellobiose, consists of two molecules of glucose. For this reason, cellulose can also be considered as a (syndiotactic) polyacetal of glucose.

Basic Structure. The basic chemical formula of cellulose is the following:

$$C_{6P}H_{10P+2}O_{5P+1} \approx (C_6H_{10}O_5)_P \text{ or } (C_6H_{10}O_5)_n$$

where *P* = the degree of polymerization; *n* = the number of units in the chain.

The elemental composition of 44.4 % C, 6.2 % H, and 49.4 % O was already known to PAYEN in 1842 [9]. The molecular

mass of the glucose base unit is m_0 = 162, and the molecular mass of the cellulose polymer is

$$M_r = m_0 P + 18 \approx 162 P$$

Constitutional Formula. HAWORTH [10] first discovered the covalent bonds inside and between the glucose units while STAUDINGER [11] found the final proof for the macromolecular nature of the cellulose molecule.

Conformational Formula. The glucopyranosic ring adopts a $^4c_1$ chair conformation, as revealed by X-ray crystallography and nuclear magnetic resonance studies [12], [13] with glucose. The chair formation in comparison to the tray conformation exhibits a free stabilization enthalpy of G_s = 20.05 kJ/mol [14]. In this conformation, the three hydroxyl groups are positioned in the ring plane while the hydrogen atoms are in a vertical position. It seems only natural to assume that the same conformation also exists in the cellulose molecule.

Structural Anomalies. As a naturally occurring polymer, cellulose always contains small amounts of other constituents in addition to glucose (over 99 %). These may already be partially built into or onto the cellulose molecules during biosynthesis, such as lignin – cellulose complexes [15]. Most of the changes in the molecular structure, however, result from secondary reactions, i.e., hydrolysis or oxidation, during isolation from natural sources. For morphological reasons, such chemical changes occur preferably in the accessible interlinking regions between the crystallites of the elementary fibrils or their aggregations. The glucosidic links in these accessible areas, especially if oxidized sites are also present, split 1 000 – 5 000 times faster than glucosidic linkages inside the well-ordered crystallites. The existence of weak links, as proposed in reference [16], is hard to determine. In homogeneous acid hydrolysis, all glucosidic linkages split at the same rate [17].

Cellulose always contains carboxyl groups: In wood pulp, one –COOH group per 100 – 1000 anhydroglucose units (AHG) exists; in cotton, one –COOH group per 100 – 500 AHG units.

Molecular Size. The molecular size of a polymer can be defined by its average molecular mass ($\bar{M}_r$) or its average degree of polymerization ($\bar{P}$); whereby $\bar{M}_r = \bar{P}\, m_0$ (m_0 = molecular mass of the base unit, i.e., of glucose in the case of cellulose).

By investigation of certain physical properties of cellulose or polyhomologous cellulose derivative solutions, the average degree of polymerization can be determined. Table 1 lists the number average degree of polymerization of a number of celluloses of various origin.

Table 1. Degree of polymerization of celluloses of different origin [18]

Type of cellulose	$\bar{P}_n$
Cotton, raw	7 000
Cotton, raw (according to Russian work)	14 000
Cotton, purified	1 500 – 300
Cotton linters	6 500
Flax	8 000
Ramie	6 500
α-Cellulose (isolated from wood fibers)	1 100 – 800
Spruce, pulped	3 300
Beech, pulped	3 050
Aspen	2 500
Fir	2 500
Bacterial cellulose	2 700
Acetobacter cellulose	600

For such physical investigations, cellulose solutions in aqueous copper(II)tetrammonium hydroxide (Schweitzer's reagent; Cuoxam), copper(II)ethylenediamine hydroxide (Cuen), alkaline solutions of the ethylenediamine complexes of cadmium or

nickel can be used. Cellulose trinitrate (CTN) or cellulose tricarbanilate (CTC) solutions in appropriate solvents are also suitable for such studies (see Table 2). In the latter, it should be kept in mind that chain degradation often occurs in substitution reactions performed under unfavorable conditions.

Light scattering studies performed on dilute solutions of cellulose or cellulose derivatives will yield the weight average ($\bar{M}_w$) and osmotic measurements the number average ($\bar{M}_n$) of the molecular mass (or the corresponding average degrees of polymerization: $\bar{P}_w$ or $\bar{P}_n$). Sedimentation experiments in an ultracentrifuge enable the determination of a higher order average molecular mass, the so-called "Z-average" ($\bar{M}_z$). These various quantities are defined as follows:

$$\bar{M}_w = \frac{\sum N_i \cdot M_i}{\sum N_i} \quad \text{or} \quad P_w = \frac{\sum N_i \cdot P_i}{\sum N_i} \quad \text{(weight average)}$$

$$\bar{M}_n = \frac{\sum N_i \cdot M_i^2}{\sum N_i \cdot M_i} \quad \text{or} \quad P_n = \frac{\sum N_i \cdot P_i^2}{\sum N_i \cdot P_i} \quad \text{(number average)}$$

$$\bar{M}_z = \frac{\sum N_i \cdot M_i^3}{\sum N_i \cdot M_i^2} \quad \text{or} \quad P_z = \frac{\sum N_i \cdot P_i^3}{\sum N_i \cdot P_i^2} \quad \text{(Z-average)},$$

whereby $M = 162\,P$; i = fraction $1, 2, 3 \ldots i$; N = number of molecules with $M_1, M_2 \ldots M_i$ or $P_1, P_2 \ldots P_i$.

The simplest and most widely applied practical method for the determination of the degree of polymerization is based on measuring the "intrinsic viscosity η" (Staudinger index). The intrinsic viscosity expresses the reduced viscosity of a solution at an infinitely small concentration. The latter can be derived from the relative viscosity, which is the ratio of the flow time of the dilute polymer solution of a given concentration (t_{ps}) and that of the solvent (t_s) in a capillary viscometer:

$$\eta_{rel} = t_{ps}/t_s$$

$$\eta_{red} = \frac{\eta_{rel} - 1}{c}$$

wherein c = concentration of the cellulose or its derivative in the solution.

The degree of polymerization can be calculated from [η] by using the formula:

$$[\eta] = \lim_{c \to 0} \eta_{red} = K_p P_v^a \text{ (or } K_m M_v^a)$$

The definition of $\bar{P}_v$ (viscosity average of the degree of polymerization) is as follows

$$P_v = \left\{ \frac{w_i P_i^{1+a}}{w_i P_i} \right\}^{1/a}$$

wherein w_i = weight fraction of a molecularly uniform fraction with a degree of polymerization of P_i; $\bar{P}_v$ = viscosity average of the degree of polymerization which for cellulose or cellulose derivative solutions closely resembles the weight average $\bar{P}_w$; and $\bar{M}_v$ = viscosity average of the molecular mass.

Table 2 summarizes some of the more important a, K_m, and K_p values. These values have been obtained by calibration to one of the above-mentioned absolute methods for the determination of the degree of polymerization.

Table 2. Values for the constants *a*, K_m, and K_p [19], [20] (concentration in g/mL)

	Solvent system	*T*, °C	*a*	K_m, ×10^5	K_p, ×10^3
Cellulose	cuoxam	20	0.9	5.54	5.40
Cellulose	cuen	25	0.9	12.5	11.07
Cellulose	cadoxen	20	1.0	3.14	5.09
Cellulose	iron – sodium tartrate	20	1.0	4.08	6.61
CTN	acetone	25	1.0	2.8	4.54
CTN	acetone	25	0.93	7.1	8.06
CTN	butyl acetate	25	1.0	2.8	4.54
CTN	ethyl acetate	25	0.76	37.1	60.10
CTN	ethylene chlorohydrine	25	0.83	15.5	10.57
CTC [20]	acetone	25	0.91	143	146.6
CTC [20]	dioxane	25	0.97	81.3	113.1

Quite often one speaks simply of the "average degree of polymerization" (DP), which is misleading, however, unless the method of determination is properly stated ($\bar{P}_n$, $\bar{P}_w$, $\bar{P}_z$, or $\bar{P}_v$).

Polymolecularity. Cellulose isolated from its native sources is always polydisperse; i.e., it consists, as do all polymers, of a mixture of molecules with the same basic composition and chemical constitution but differing widely in their chain length or degree of polymerization, respectively. The relative amounts of molecules of various lengths present in a given cellulose substrate can be specified by the so-called differential mass distribution curves. Unlike most synthetic polymers, cellulose substrates have complicated mass distribution functions. Figure 1 shows typical mass distributions of various cellulose samples.

Figure 1. Differential mass distribution curves of various celluloses [18]

a) Cotton; b) Cotton; c) China grass (ramie); d) Flax; e) Ramie; f) Balsam; g) White fir; h) Birch

Knowledge of the molecular mass distribution is important for many applications. However, most of the methods applied in the past, such as fractionation by precipitation or selected dissolution, consume a great deal of time and are often subject to objection. In recent years, gelpermeation chromatography, especially in combination with low-angle laser light scattering, was developed to such a state as to provide a fast and highly reproducible method for this purpose [21].

As a convenient measure of the broadness of the mass distribution, the so-called nonuniformity factor (NU) is often used:

$$\mathrm{NU} = P_w / P_n - 1$$

A polymer with a normal (most probable) molecular mass distribution will have a nonuniformity factor of 1. In most cases, cellulose substrates show much higher molecular nonuniformities.

Secondary Structure. In solution, the cellulose molecules exist in form of largely expanded coils. In addition to isolated and solvated molecules, cellulose and cellulose derivative solutions frequently also contain supermolecular gel particles, so-called micelles [22].

In solid cellulose, high-order microcrystalline structures (“crystalline regions”) alternate with those of a distinctly lower order (“amorphous regions”). Cellulose is polymorph; i.e., depending on the origin or the conditions during isolation or conversion, cellulose will have or can adopt various crystal lattice structures.

Lattice Structure. Native celluloses all show the so-called cellulose I lattice structure. Each unit cell houses two countercurrently arranged cellulose molecules. The lattice of cellulose I is of the monoclinic sphenolitic type. The cellulose chains are in line with the *b* axis of the unit cell. Figure 2 shows a schematic of the unit cell of the cellulose I modification.

Figure 2. A) Unit cell of the crystal lattice of cellulose I

B) Comparison of the unit cell cross-sections of the native cellulose I and mercerized cellulose II

The cellulose molecules are aligned in the fibrillar axis and form the *b* axis of the unit cell. The length of the *b* axis is 1.03 nm (10.3 Å), somewhat shorter than the extended length of a cellobiose unit, which suggests a slight helical twist in the cellulose chains along the *b* axis [23-25]. This twist is caused by intramolecular hydrogen bonding primarily between the hydroxyl groups on the carbon atom C–3 of one glucose unit and the pyranose ring oxygen in the adjacent glucose unit of the same chain molecule. This intramolecular secondary valence bond is also responsible for the relative rigidity of the cellulose molecule [26]. Some authors [27] suggest a second intramolecular hydrogen bond involving the hydroxyl groups on C–6 and C–2 of adjacent glucose units in the same molecule.

In more recent years, some researchers suggested a unit cell for cellulose I in which the *a* and *c* axis of the Meyer–Mark–Misch model are doubled [28], [29]. However, these newer interpretations of X-ray and electron diffraction results are more or less closely related to the Meyer–Mark–Misch lattice structure. In reference [30], it is claimed that there is a closer agreement with the observed diffraction intensity data for parallel arrangement of the cellulose molecules in the unit cell. However, this is still controversial [31].

The internal cohesion of the cellulose molecules in the unit cells and crystalline domains is due to intermolecular secondary valences — partly hydrogen bonds and partly van der Waal's forces. These bonds can act either between molecules situated in the same crystal lattice plane (intraplanar bonds) or between molecules located in neighboring lattice planes (interplanar bonds). The intraplanar hydrogen bonds are formed primarily between adjacent cellulose molecules in the same 002 lattice planes giving a sheetlike structure. The 002 sheets are then bonded to one another by hydrogen bridges involving the hydroxyl groups on C–6 and the glucosidic ring oxygen atoms of cellulose molecules favorably located in neighboring 002 planes, or by van der Waal's forces acting between neighboring glucopyranose rings.

The unit cells of the other polymorphic structures of cellulose — the most important one being the so-called cellulose II — differ basically in the lengths of their *a* and *c* axis and the angle of inclination β. The cellulose II modification is formed as the thermodynamically most stable polymorph when cellulose fibers are treated with concentrated sodium hydroxide solution (> 14 %) or precipitated (regenerated) from solution.

In addition to the cellulose I and cellulose II modifications, two other polymorphic lattice structure are known, the cellulose III and cellulose IV crystal modifications. The cellulose III structure is formed when the reaction product of native cellulose fibers is decomposed with liquid ammonia. This modification has a lattice structure closely related to that of cellulose II. The cellulose IV modification is obtained by treating regenerated cellulose fibers in hot baths under stretch. The lattice of this polymorph is closely related to that of cellulose I. Some distinct differences in their infrared absorption spectra seem to indicate their existence. Some researchers however doubt their actual existence [32].

Table 3 lists the lattice parameters of the unit cells of these four polymorphic crystal structures.

Table 3. Lattice parameters of the unit cells of the cellulose polymorphs

Type	Source	Dimensions, nm			
		a	b	c	β, degree
Cellulose I	cotton	0.821	1.030	0.790	83.3
Cellulose II	cotton, mercerized	0.802	1.036	0.903	62.8
	viscose fiber	0.801	1.036	0.904	62.9
Cellulose III		0.774	1.030	0.990	58.0
Cellulose IV		0.812	1.030	0.799	90.0

Crystallites. The ability of hydroxyl groups to form secondary valence hydrogen bonds is – together with the stiff and straight chain nature of the cellulose molecule – the cause for the high tendency to organize into crystallites in parallel arrangement and crystallite strands (elementary fibrils), the basic elements of the supermolecular structure of cellulose fibers.

The dimensions of the elementary crystallites differ only slightly for native or regenerated cellulose fibers. Their length ranges between 12 and 20 nm (= 24 – 40 glucose units) and their width between 2.5 and 4.0 nm. The often observed larger “micro- or macrofibrils” (or fragments thereof) are aggregations of elementary fibrils.

Two questions concerning the crystal structure are still under dispute. The first deals with the antiparallel or parallel arrangement of the cellulose molecules in the crystal lattice as previously mentioned. The second question (still open) concerns the existence or nonexistence of folded chains in the lattice [33-35]. While a folded cellulose chain position in the lattice seems unlikely to most experts, the parallel molecule arrangement in the cellulose I lattice is principally acceptable, under the condition that two cellulose II lattice structures exist, one for heterogeneously mercerized native celluloses with parallel arrangement of the molecules and the other for regenerated cellulose substrates with antiparallel molecule arrangement.

1.1.2. *Supermolecular Structure (Texture)*

The basic structural element of cellulose fibers is the so-called elementary fibril. It can be seen with the electron microscope, as illustrated in Figure 3.

Figure 3. Electron micrograph of the fibrillar nature of cellulose fibers

The cross-dimensions of the elementary fibrils correspond with those of the elementary crystallites. The elementary fibril is a strand of elementary crystals linked together by segments of long cellulose molecules. The lateral order in the interlinking regions is distinctly less pronounced (amorphous). This structure is schematically shown in Figure 4 [36-39].

Figure 4. The architecture of elementary fibrils and microfibrils of native celluloses

Several elementary fibrils associate to form larger aggregations of so-called microfibrils and macrofibrils, which can also be seen with a light microscope.

The elementary fibrils and their aggregations are determined by nature in such native fibers as cotton or wood pulp fibers and are laid down in various cell wall layers in a typical manner [18], [19]. Figure 5 shows the structural organisation of wood pulp and cotton fibers.

Figure 5. Positioning of the cellulose fibrils in wood (left) and cotton fibers (right)

Wood fibers: M) Middle lamella (lignin and hemicelluloses); P) Primary wall (fibril position unarranged); S_1) Secondary wall I (two or more fibrillar layers crossing one another and positioned spirally along the fiber axis); S_2) Secondary wall II (fibrils wound spirally around the fiber axis); S_3) Secondary wall III (fibrils tightly interlaced)

Cotton fibers: P) Primary wall (interlaced fibrils); S) Secondary wall (fibrils wound spirally around the fiber axis; in distinct distances along the fiber axis the spiral reverses direction)

Synthetic cellulose fibers, such as viscose, do not have a native morphology. Their supermolecular structure can be described as a network of elementary fibrils and their more or less random associations. This is called a “fringe fibrillar” structure [40], which is shown in Figure 6.

Figure 6. Fringe fibrillar model of fiber structure

Structure Characterization. The methods used to characterize the molecular and fine structure of native and synthetic cellulose fibers include the following [41]:

1. determination of the average degree of polymerization ($\bar{P}_n$) by the osmotic method;
2. determination of the average crystallite length by meridional X-ray low-angle scattering on slightly hydrolyzed fiber samples or by measurement of the band width of the meridional 040 X-ray wide-angle reflection at half-maximum intensity;
3. determination of the degree of order (“crystallinity,” CrI) with a method for separating overlapping equatorial X-ray diffractions [42] and deriving from the band width at half-maximum intensity the average cross-dimensions of the crystalline regions; furthermore, this analysis yields information on the lattice structure, polymorphic composition, and accessibility;
4. determination of the degree of orientation by measuring the azimuthal intensity distribution of major equatorial X-ray diffraction arcs or by IR dichroism.

Structure and Properties. Physicomechanical properties of cellulose fibers such as tenacities, elongations, or moduli in the conditioned or wet state are determined by the following structural parameters [43]: 1) the average length of the fiber-forming molecules ($\bar{P}_n$); 2) the average length of the elementary crystallites ($\bar{P}_{nL}$ = number average “limiting” degree of polymerization); 3) the degree of lateral order (crystallinity, CrI); 4) the degree of orientation (f_r) with respect to the fiber axis; and 5) the presence of heterogeneities (natural defects, incorporated gel or sand particles, etc.).

This may be illustrated by the following examples: As shown by Figure 7, the tenacity of the conditioned fibers is determined by the length of the molecules in relation to the length of the elementary crystallites building the elementary fibrils ($1/\bar{P}_{nL} - 1/\bar{P}_n$), by the degree of order (CrI), and by the degree of orientation (f_r).

Figure 7. Relation between structure parameters and tenacities of regenerated cellulose fibers

a) Regular viscose fiber; b) Medium-strength viscose fiber; c) High-strength viscose fiber; d) High-wet-modulus viscose fiber; e) Polynosic type viscose fiber; f) Medium-strength viscose tire cord; g) High-strength viscose tire cord; h) Meryl fiber; i) Fortisan fiber

The elongation at break in the conditioned state is mainly dependent on the degree of orientation. Simple geometric considerations give the parameter ($1/\cos\alpha - 1$) in which the angle α derived from the orientation factor (f_r) is the mean angle of deviation of the basic structure elements from the fiber axis. Figure 8 illustrates the relation of this parameter to the breaking elongation of a number of cellulosic fibers.

Figure 8. Relation between the degree of orientation and breaking elongation of regenerated cellulose fibers (α = average deviation of structure units from the fiber axis in degree)

a) Regular viscose fiber; b) Medium-strength viscose fiber; c) High-strength viscose fiber; d) High-wet-modulus viscose fiber; e) Polynosic type viscose fiber; f) Medium-strength viscose tire cord; g) High-strength viscose tire cord; h) Meryl fiber; i) Fortisan fiber

The wet moduli of the various fibers show a close relation to the product of the length of the elementary crystallites ($\bar{P}_{nL}$), the

degree of order (CrI), and the square of the orientation factor (f_r^2). This is demonstrated in Figure 9.

Figure 9. Relation between structure parameters and wet modulus of regenerated cellulose fibers

a) Regular viscose fiber; b) Medium-strength viscose fiber; c) High-strength viscose fiber; d) High-wet-modulus viscose fiber; e) Polynosic type viscose fiber; f) Medium-strength viscose tire cord; g) High-strength viscose tire cord; h) Meryl fiber; i) Fortisan fiber

1.1.3. *Physical Properties*

Cellulose is relatively hygroscopic. Under normal atmospheric conditions (20 °C, 60 % relative humidity), it adsorbs ca. 8 – 14 % water. Cellulose swells in water (see Table 4). It is, however, insoluble in water or dilute acids. In concentrated acids, solution can be achieved under severe degradation. Caustic solutions cause extensive swelling and dissolution of low molecular mass portions ($P \leqq 200$). Solvents for cellulose are listed in Table 2).

Table 4. Swelling of various celluloses in water

Type	Swelling, %
Cotton	18
Viscose, continuous filament	74
Cuprammonium rayon	86
Cellulose triacetate	10
Cellulose tripropionate	2.5
Cellulose tributyrate	1.8
Cellulose trivalerate	1.6
Cellulose tristearate	1.0

Cellulose is nonmelting; thermal decomposition starts at 180 °C; the ignition point is > 290 °C. With chlorine and zinc iodide, cellulose takes on a red-violet to blue color; with phloroglucinol–hydrochloric acid, pure cellulose should not take on a red color (test for residual lignin). Additional data:

Density: 1.52 – 1.59 g/cm^3
Refractive index:
1.62 parallel to the fiber axis
1.54 perpendicular to the fiber axis
Dielectric constant: 2.2 – 7.2 (at 50 Hz) Highly dependent on humidity conditions
Insulation resistance: 10^{14} – 10^{17} Ω cm Highly dependent on humidity conditions
Electric strength: 500 kV/cm
Heat of combustion: 17.46 J/g
Heat of crystallization: 18.7 – 21.8 kJ/mol of glucose
Specific heat: 1.00 – 1.21 J g^{-1} K^{-1}
Coefficient of thermal conductivity:
0.255 kJ m^{-1} h^{-1} K^{-1} (loosely packed) to
0.920 kJ m^{-1} h^{-1} K^{-1} (compressed)
Specific internal surface: 10 – 200 m^2/g

1.1.4. *Chemical Properties*

The chemical reactivity of cellulose is determined to a large extent by the supermolecular structure of its solid state. Most of the reactions on cellulose fibers are heterogeneous in nature. The reaction medium acts on a two-phase solid system: (a) the less-ordered (amorphous) regions which are mainly located on the surface of the elementary fibrils or their aggregations and in the interlinking regions between the elementary crystallites in the fibrils, and (b) the well-ordered elementary crystallites or fused associations of the elementary fibrils. Any reaction will first start on the less-ordered surface of the elementary fibrils or their aggregations (topochemical reaction) and then, under favorable conditions, proceed into the interlinking regions between the elementary crystallites to penetrate from both ends into the crystallites. Therefore, as long as the reaction is limited to the accessible surface of the fibrils or fibrillar aggregations and the regions interlinking the elementary crystallites (i.e., up to degrees of substitution (DS) of 1.3 – 1.7), there is no visible effect in the crystalline structure. At increased degrees of substitution (to ca. DS = 2.5), the X-ray diffractogram shows overlapping diffraction bands of the original cellulose I structure and the cellulose derivative. At still higher degrees of substitution, the pure diffraction pattern of the derivative will finally result. This course of reaction implies that partially substituted cellulose derivatives are always a mixture of completely substituted cellulose, partially substituted portions (of block-polymer nature), and unsubstituted cellulose.

A quasi-homogeneous reaction can be achieved when the fiber structure is loosened by swelling treatments to such an extent that all cellulose molecules can react simultaneously. A real homogeneous reaction can, however, only be achieved

by bringing the cellulose into a molecularly dispersed solution.

The reactivity of cellulose substrates can be greatly enhanced by activation treatments, such as swelling, solvent exchange, inclusion of structure-loosening additives, degradation, or mechanical grinding, which enlarge accessible surfaces by opening fibrillar aggregations. These treatments also restore, in most cases, the loss of reactivity due to so-called hornification, which occurs when water is removed from cellulose by drying under severe conditions.

Swelling with water or other polar liquids is the most frequently applied activation treatment. It exclusively opens the interfibrillar interstices and swells the less-ordered surface and interlinking regions of the fibrillar elements. The solvent exchange technique is a special kind of activation from the water-swollen state. It allows the introduction of media being inert in subsequent reactions that are unable to swell the cellulose substrate thus maintaining the reactive water-swollen state. An interesting variation of the solvent exchange treatment is the so-called inclusion technique [44]. Inert liquids, such as cyclohexane or benzene, are introduced into the cellulose substrate by solvent exchange from the water-swollen state. During drying, they are permanently incorporated into the interfibrillar interstices or voids, thus preventing fusion of fibrils, i.e., the hornification. Such inclusion celluloses are very reactive, as shown in Table 5.

Table 5. Acetylation of vacuum-dried native and mercerized cotton after inclusion of benzene using acetic anhydride – sulfuric acid at 60°C

Time of acetylation	Native		Mercerized	
	P 2500	*P* 340	*P* 2200	*P* 290
	% Acetyl			
Acetylated after vacuum drying:				
24 h	2.0	5.6	0.9	1.3
48 h	3.8	8.3	1.9	2.9
96 h	6.8	12.5	2.5	3.6
192 h	14.2	21.9	3.0	4.8
408 h	37.8	39.9	11.0	14.5
Acetylated after benzene inclusion, benzene wet:				
1 h	19.4	19.1	25.7	24.3
24 h	42.5	44.1	45.0	44.7
Acetylated after benzene inclusion and drying:				
1 h	17.3	16.8	23.9	23.0
24 h	41.5	42.1	43.2	43.1

Another very effective way of activating cellulose fibers is to enhance the accessibility of fibrillar surfaces and to open the less-ordered regions interlinking the crystallites in the fibrils by treatment with systems causing not only interfibrillar, but also intracrystalline, swelling. Some inorganic acids, various salt solutions, and especially certain inorganic and organic bases achieve this at distinct concentrations. They apparently penetrate the fiber through existing capillaries and pores by opening the fibrillar interstices and entering the interlinking regions between the crystallites. From there, they enter the elementary crystallites from both ends and force them open. At suitable concentrations and temperatures, they ultimately cause crystal lattice transfer, particularly with respect to opening the 101-plane distances (see Table 6).

Table 6. Effect of swelling agents on the (101) interplanar spacing of cellulose [45]

Swelling agent	Observed (101) distance, nm
Liquid ammonia	1.03 – 1.06
Methylamine	1.467
Ethylamine	1.572
n-Propylamine	1.848
n-Butylamine	1.973
n-Amylamine	2.192
n-Hexylamine	2.485
n-Heptylamine	2.874
Hydrazine	1.03

Ethylenediamine	1.226
Tetramethylenediamine	1.465
Tetramethylammonium hydroxide	1.30
Ethyltrimethylammonium hydroxide	1.30
Benzyltrimethylammonium hydroxide	1.65
Dibenzyldimethylammonium hydroxide	1.65

So-called mercerization is a frequently used practical method of activation, i.e., the treatment of native cellulose substrates with 10 – 20 % sodium hydroxide solutions at moderate temperature (< 20 °C). In this treatment, sodium cellulose I is formed in which the 101-plane distance is increased from 0.61 nm (6.1 Å) in native cellulose to 1.22 nm (12.2 Å). In this lattice transition, the glucopyranose rings are dislocated and aligned into the 101 lattice plane. The hydroxyl groups on the C–2 and C–6 carbon atoms are thus freely exposed and jut into the widened space between the 101 lattice planes, making them accessible for reactions.

The chemical character of cellulose is determined by the sensitivity of the β-glucosidic linkages between the glucose repeating units to hydrolytic attack and the presence of one primary and two secondary reactive hydroxyl groups in each of the glucopyranose units. These reactive hydroxyl groups are able to undergo exchange, oxidation, and substitution reactions, such as esterification and etherification.

Sorption and Exchange Reactions. Cellulose undergoes sorption and exchange reactions with water and deuterium oxide. These reactions are of special interest since they give a good indication of the accessibility of the cellulose substrate.

The cross-dimensions of the well-ordered regions can be derived from the width of the equatorial X-ray wide-angle diffractions. If it is assumed that the crystallites are surrounded by one layer of disturbed ("amorphous") unit cells and also that the molecules in the next outer layer of the well-ordered crystalline core of the crystallites are in addition accessible for reactants such as water or deuterium oxide, an explanation for the extent of water adsorption and deuterium exchange should be possible, see Figure 10 [46].

Figure 10. Model of crystallinity (left) and accessibility (right) of fibrils in a high-wet-modulus viscose staple fiber [46]

Table 7 compares the experimentally obtained water sorption and deuterium exchange values with those predicted from structure investigations according to the above outlined concept.

Table 7. Crystallinity and accessibility of cellulose substrates from X-ray diffraction in relation to H_2O adsorption and deuterium exchange

Sample	Relative dimensions [a]			% molecules in:			Deuterium exchange, %	H_2O adsorption	
	101	101	002	Ordered regions	Amorphous regions	Accessible regions		Theoretical [b], %	Experimental, %
Cotton	200	155	230	83	17	47		7.8	8.1
Fortisan	140	100	160	80	20	54	53.5	9.0	9.6

[a] Derived from X-ray wide-angle diffractograms corrected for the band-widening effects of sample size and beam dimension.
[b] Calculated by assuming that accessible glucose units bind 1.5 mol of H_2O each.

The internal surface data calculated from crystallite cross-dimensions are also in good agreement with those determined by gas adsorption.

Degradation by Acid Hydrolysis. Degradation in acidic medium is based on the hydrolysis of the β-glucosidic linkages between the glucose base units. The reaction depends strongly on pH and already proceeds at a remarkable rate at low pH and temperatures well under 100 °C. Initially the acetal oxygen of the glucosidic linkage is protonated. Through heterolysis, an intermediate carbonium ion is formed, causing chain-splitting. The carbonium ion finally reacts with water, which reforms

the proton. The following reaction scheme illustrates the course of this reaction.

Homogeneous and heterogeneous hydrolysis of cellulose are both first-order reactions. The reaction speed is strongly dependent on the acid and the cellulosic material. The course of homogeneous and heterogeneous hydrolysis also reveals a basic difference. In homogeneous hydrolysis degradation proceeds at a constant rate until all of the cellulose is degraded to cellobiose or glucose, respectively. In heterogeneous hydrolysis, the rate decreases continuously and degradation stops almost completely when the number-average degree of polymerization reaches 25 – 100. This corresponds to the length of the elementary crystallites ("level-off degree of polymerization"). Hydrolysis proceeds thereafter at a very slow rate. It is interesting to note that during the course of homogeneous hydrolysis, the degraded and isolated residue adopts an increasingly normal molecular mass distribution as indicated when the ratio of its weight to the number average degree of polymerization approaches a value of 2. This is indicative of a statistical degradation (see Table 8).

Table 8. Comparison of the changes in molecular non-uniformity during the course of homogeneous and heterogeneous degradation of cellulose [47], [48]

Time, min	$\bar{P}_w$	$\bar{P}_n$	$\bar{P}_w/\bar{P}_n$
Homogeneous hydrolysis in H_3PO_4 at 25 °C			
0	1600	1245	1.29
60	1055	785	1.34
210	610	410	1.50
750	260	150	1.73
2100	100	55	1.82
Heterogeneous hydrolysis with 1 N HCl at 50 °C			
0	1750	1200	1.46
180	800	560	1.43
540	440	310	1.41
1620	250	180	1.38
3240	120	95	1.26

In contrast, the residue in heterogeneous hydrolysis tends toward a value of 1 for the ratio of its weight to number-average molecular mass. This is a strong indication that the course of heterogeneous degradation is not determined solely by the sensitivity of the β-glucosidic linkages, but primarily by morphological aspects [49]. Hydrolytic attack is almost completely limited to the molecules situated on the surface of the fibrillar strands and the accessible molecule segments connecting the crystallites. It is also important to note that mass loss in heterogeneous hydrolysis performed under moderate conditions is relatively small in the initial fast reaction.

Degradation in Alkaline Media. Hydrolysis of the β-glucosidic linkages in alkaline media occurs at a significant rate only at temperatures above 150 °C. It is most probable that chain-splitting proceeds by way of the 1,2-anhydro configuration [50].

Acidic as well as alkaline hydrolysis of the glucosidic bond is remarkably enhanced (β-elimination) by oxidative changes at the C–2, C–3, or C–6 carbons leading to carbonyl groups. An example of this chain-splitting reaction, which can even occur at moderate temperatures, is [51]:

An additional degradation reaction taking place in alkaline media is the so-called peeling reaction. In the course of this reaction, which even takes place at temperatures well below 100 °C, the cellulose chain molecules are degraded step-by-step, beginning at the reducing end and proceeding in a “zipper-like” reaction. The terminal glucose unit is first transformed into the 1,2-enediol, which isomerizes to the corresponding ketose and splits off the chain. The ketose is transformed further into the alkali-stable isosaccharinic acid [52].

The newly formed aldehydic end of the cellulosic chain will repeat the same reaction. When ca. 50 – 60 glucose units are split off under these conditions, the reaction normally stops due to the interference of a chain-stopping reaction. This termination reaction leads by way of the 2,3-enediol to an alkali-stable metasaccharinic acid end group, which stabilizes the cellulose molecules against further degradation.

The degradation in acidic as well as in alkaline media is of great importance in the manufacture of pulp from wood and other plants and in the processing of cellulose derivatives, regenerated fibers, and films.

The microbiological degradation of cellulose should also be mentioned in this connection. This degradation takes place through enzymatic hydrolysis of the β-glucosidic linkages and is of interest in connection with the use of plant biomass [53].

Oxidation Reactions. The hydroxyl groups and the aldehydic end groups participate in the oxidation reactions of cellulose. These reactions form aldehyde, ketone, and carboxyl groups. Extensively oxidized and degraded products are designated as oxycelluloses. Some oxidizing agents show specific action. They attack only specific functional groups, forming defined oxidation products. Other oxidants react nonspecifically with all types of oxidizable groups in the cellulose molecules. Under special conditions hypoiodite and chlorite attack only the aldehyde end group on C–1, oxidizing it to form a carboxylic group. Another oxidant with specific action is periodate, which attacks the glycol configuration on the carbon atoms C–2 and C–3, thus causing ring-splitting and forming a dialdehyde structure.

Nitrogen dioxide (dinitrogen tetroxide) reacts not quite as specifically. It oxidizes, however, with a certain preference the hydroxyl group on C–6 to a carboxyl group and to a lesser extent hydroxyl groups on C–2 and C–3 to ketone groups.

Nonspecific oxidants are chlorine, hypochlorite and chromic acid. They also oxidize all accessible hydroxyl groups to aldehyde, ketone, and carboxyl groups. The oxidative action of chlorine and hypochlorite is extensively used as a bleaching agent in the pulp industry. However, one must keep in mind that the introduction of carbonyl groups on C–2, C–3, and C–6 causes alkali instability of glucosidic linkages in the β-position which initiates degradation under alkaline conditions.

Esterification and Etherification. Both of these substitution reactions are used in industry for the manufacture of widely used products (⟶ Cellulose Esters, ⟶ Cellulose Ethers). The acetate and nitrate esters and the methyl and carboxymethyl ethers of cellulose, and to a lesser extent the ethyl and hydroxyethyl ethers, have acquired practical significance.

To perform the esterification or the etherification reaction properly, the hydroxyl groups in the cellulose substrate must be made accessible for the reaction. The supermolecular structure of the cellulose must be activated before or in the course of the substitution reaction. For this purpose the cellulose substrate is treated with strong acids or alkali. In these treatments addition compounds are formed between the cellulose, acid, or alkali and the water present in the system. During the opening of hydrogen bonds between the molecules in the cellulose substrate, more or less defined addition compounds are formed in the crystalline regions. Their formation is often accompanied by changes in the lattice structure, resulting mostly in an increased distance between the 101 planes. This exposes the hydroxyl groups on C–2 and C–6, making them accessible. Hydrated cations or anions of the reactant, respectively, are incorporated into the widened interplanar space, where they initiate and facilitate the reactions. The addition compounds thus formed are only stable in equilibrium with the reactant and will decompose readily when the system is diluted with water.

The basic principle of the esterification and etherification reaction is quite similar. The first step is a nucleophilic substitution or addition and the formation of an oxonium ion on the carbon atom carrying the reactive hydroxyl group. A surplus of esterification or etherification reactant will lead to the formation of the corresponding ester or ether:

1. General esterification mechanism (formation of an oxonium ion; inorganic acid esterification)
2. Esterification with organic acids (nucleophilic addition)
3. Acid-catalyzed esterification
4. General etherification mechanism (formation of an oxonium ion; alcohol excess leads to ether formation)
5. Etherification of cellulose with alkali consumption
6. Etherification of cellulose without alkali consumption

The esterification reaction is promoted by water-binding catalysts. In etherification, prior swelling of the cellulose substrate with alkali or the transfer to alkaline cellulose is essential for the reaction.

The presence of three hydroxyl groups in each glucose unit allows the formation of mono-, di-, and triesters or ethers, respectively. Contrary to the reaction behavior of primary and secondary hydroxyl groups in low molecular mass alcohols, where the primary hydroxyl group always shows a higher reactivity, the secondary hydroxyl group on C–2 quite often shows preferred reactivity in heterogeneous esterification or etherification of cellulose. Table 9 illustrates this for the relative reaction rate of the hydroxyl groups on C–2, C–3, and C–6 in various etherification reactions [54].

Table 9. Relative etherification velocities at the OH-groups on C–2, C–3, and C–6

Derivative	K_2	K_3	K_6
Methylcellulose	5	1	2
Ethylcellulose	4.5	1	2
Carboxymethylcellulose	2	1	2.5
Hydroxyethylcellulose	3	1	10
Cyanoethylcellulose	3	1	3

The normally expected preferred reactivity of primary hydroxyl groups on C–6 can be observed only in substitution reactions on cellulose in solution. The fact that most substitution reactions on cellulose are performed in heterogeneous systems also has the consequence that most partially substituted cellulose derivatives are actually mixtures of fully substituted, irregularly substituted (block substitution), and unsubstituted cellulose molecules.

The extent of substitution in cellulose derivatives is described by the so-called “degree of substitution” (DS). This value states the average number of substituents linked to each glucose base unit in the cellulose molecules. Since substitution normally occurs irregularly along the cellulose chains, the DS can assume any value between 0 and 3.

Industrially produced cellulose esters and ethers find practical use as fibers, films, lacquers, explosives, adhesives, and as auxiliaries in paper, textile, and food industries. Their properties and, consequently, their applications are primarily dependent on the nature of the substituents, the degree of substitution, the distribution of substituents along the cellulose molecules and from molecule to molecule, and their degree of polymerization.

In particular, the xanthation of cellulose is of great economic importance, i.e., the esterification with dithiocarbonic acid. This reaction is the basis for the so-called viscose process, which is widely used for the manufacture of regenerated cellulose fibers and films (see Chap. Regenerate Cellulose). The cellulose xanthate is obtained in the reaction of alkali cellulose with carbon disulfide and is soluble even in dilute sodium hydroxide solutions at relatively low degrees of substitution (DS < 1).

Graft Copolymerization. During the last two decades, another way of modifying cellulose, the grafting reaction, has found substantial interest. This method allows the attachment of chemically different side-chains to a given polymer molecule. The reaction mechanisms are principally the same as in the synthesis of polymers [55], [56]. The most frequently used method is to initiate grafting with radical catalysts. To achieve graft copolymerization, the cellulose substrate must be in the presence of peroxides or redox systems (i.e., hydrogen peroxide, hydrogen peroxide – iron(III) ions, Ce(IV) ions) and as such is able to undergo polymerization with such compounds as styrene, acrylic acid, acrylic ester, etc. The introduction of substituents that are able to enhance radical transfer, such as thiol or xanthate groups, promotes the grafting reaction. Industrial applications for graft-modified cellulose fibers are thus far very limited.

1.2. Occurrence

Cellulose is one of the main cell wall constituents of all major plants. It occurs there in varying amounts. Cellulose is found in nonlignified (such as cotton) and lignified (such as wood) secondary plant cells and constitutes as such the major portion of all chemical cell components. Table 10 lists the cellulose content of some wood species.

Table 10. Cellulose content of various wood species

Type of wood	Cellulose content, %
Spruce (*Picea abies*)	43
Pine (*Pinus silvestris*)	44
Birch (*Betula verrucosa*)	40
Beech (*Fagus silvatica*)	43
Poplar (*Populus tremuloides*)	53

The cell walls of green algae also contain cellulose. Furthermore, cellulose is also found in the membranes of most fungi and in the cell walls of some flagellates. So-called bacterial cellulose is synthesized by *Acetobacter xylinum* on nutrient media containing glucose. In the animal kingdom one finds cellulose in the tunics of the Tunicatae.

The raw material sources for industrially used cellulose are almost exclusively the fiber cells of more fully developed plants, especially cotton, bast, and leaf fibers for the textile industry, and wood and some other graminaceous plant fibers (i.e., grain straws, bamboo canes, and sugar cane wastes) for the paper industry. Wood consists of up to approx. 40 – 50 % cellulose. Additional wood constituents are lignin, hemicelluloses (i.e., lower molecular mass polysaccharides containing other sugars as monomer units in addition to glucose), extracts (such as resins, gums, fats, waxes, terpenes, etc.), and numerous other native organic compounds in smaller amounts.

1.3. Production

Cotton fibers and wood are the primary raw materials for the production of industrially used cellulose.

Raw cotton fibers and linters contain small amounts of proteins, waxes, pectins, and inorganic impurities in addition to approximately 95 % pure cellulose. These constituents can be removed if they interfere with the intended further processing, with relatively simple procedures. Treatments with hot alkali and subsequent bleaching with hypochlorite, peroxides, or chlorine dioxide are in use.

A sequence of processing steps is necessary for the isolation of relatively pure cellulose (pulp) from wood. To remove most of the lignin and of some of the other wood constituents, a pulping procedure has to be performed. This can either be done with sulfurous acid containing solutions of hydrogen sulfites (i.e., magnesium, calcium, sodium, or ammonium hydrogen sulfite in an excess of sulfurous acid) or with alkaline sodium hydroxide – sodium sulfate solutions at ca. 130 – 180 °C. These

treatments reduce wood chips to fibers by using a slight mechanical action. To further purify and brighten the raw pulp stock for the manufacture of paper and for chemical applications, a multistage refining procedure must follow. These refining steps consist of alkali treatments in the presence of oxidizing agents (chlorine, chlorine dioxide, hydrogen peroxide, oxygen, or air) to remove residual lignin followed by bleach sequences with hypochlorite or hydrogen peroxide. In the production of dissolving pulps for the manufacture of cellulose films, fibers, or cellulose derivatives, extractions with cold or hot alkali are used in addition to remove low molecular mass polysaccharides (hemicelluloses) and to increase the pure cellulose (α-cellulose) content. Depending on the number of refining steps and conditions, wood pulps containing up to ca. 99 % pure cellulose can be obtained. The yield from wood, however, will be ca. 70 % for the production of low cellulose content paper pulps and only 30 % for the production of pulps with high cellulose content. Cellulose content higher than 99 % is practically unachievable since the cellulose would undergo extensive degradation in such an attempt and thus be of no further use. Table 11 lists the cellulose contents (α-cellulose) of some major paper and dissolving pulps.

Table 11. α-Cellulose content of various paper and dissolving pulps

Type	α-Cellulose content, %
Paper pulps, bleached:	
Spruce, sulfite	89
Beech, sulfite	89
Spruce, sulfate	82
Birch, sulfate	72
Sulfite dissolving pulps for:	
Regular rayon staple	89 – 91
High-wet-modulus rayon staple	91 – 93
Acetate filament yarn	94 – 95
Sulfate dissolving pulps for:	
Regular rayon staple	93 – 95
High-wet-modulus rayon staple	95 – 98
Rayon tire cord (super II – III)	96 – 98
Acetate filament yarn	98

1.4. Quality Testing

The determination of the residual impurities and the extent of molecular degradation or other chemical changes of the cellulose is, in most cases, not essential for cotton fibers in the textile field or wood pulps in the paper field.

However, celluloses (cotton linters or wood pulp) which will be used either for the manufacture of regenerated cellulose and cellulose acetate fibers or for cellulose derivatives must undergo careful quality testing.

Because the first step in the further processing quite often consists of a treatment with sodium hydroxide solutions, the testing for alkali solubility is very important. The solubility in 5, 10, and 18 % sodium hydroxide solution can give a preliminary indication of the content of noncellulosic low molecular mass polysaccharides (also including low molecular mass cellulose). A more detailed determination of cellulose and noncellulosic polysaccharide content is possible after complete hydrolytic degradation to the corresponding monomeric sugars and the use of chromatographic methods.

One of the most important characteristics for the chemical processing of cellulose is the degree of polymerization (see Molecular Size.). For industrial testing practice, viscosimetric methods using standardized flow or ball-fall viscometers are quite satisfactory.

Further test methods for dissolving pulps are the determination of residual lignin, of extractables soluble in organic solvents, and of the composition of inorganic ingredients (ash). Standardized methods for all of these tests are described by ISO (International Standards Organization), ASTM (American Society for Testing and Materials), TAPPI (Technical Association of Pulp and Paper Industry, United States), DIN (German Industrial Norms), or Zellcheming (German Association of Pulp and Paper Chemists and Engineers), etc.

1.5. Applications

The greatest portion of industrially used wood cellulose by far (ca. 150×10^6 t/a) is used after partial removal of the noncellulosic constituents in its original fiber form for the production of paper, board, and nonwovens. The same applies to most of the long-haired cotton fibers (ca. 15×10^6 t/a) and their use in the manufacture of textiles. Only a minor portion (ca. 7×10^6 t/a) is used in form of high- α-cellulose wood pulps or cotton linters as starting material for the production of synthetic

cellulosic fibers, primarily viscose and acetate fibers, or regenerated cellulose films, and cellulose derivatives, especially esters and ethers. Small amounts of pure cellulose are further used in the form of microcrystalline cellulose as powder or colloidal suspensions, additives in low-calorie foodstuffs, binder for forming pharmaceuticals into tablets, and for a number of industrial uses.

[Top of Page]

2. Natural Cellulosic Fibers

Robert G. Steadman and Karl Schliefer

All plants produce cellulose, a natural polymer of the plant sugar glucose, as they mature from the “sweet” to the “stringy” phase. This stringy component, located in various parts of the plant, has long been exploited for textile and related uses, with more than 2 000 species having been spun into some kind of yarn or cord at some time or place.

Only a few of these plants are presently cultivated solely for their fibers, cotton being predominant. Few plant fibers lend themselves to home consumption. They are sold mostly as cash crops. All are obtained in impure form and require on-site processing to remove other plant components even before being shipped to spinning mills for further cleaning.

The breakdown of dead plants by bacteria, fungi, and fire is an essential stage in the life cycle of natural flora. Cellulose is thus susceptible to rot, mildew, and fire, three major shortcomings of these fibers in textiles. These problems can be overcome by the application of topical finishes.

Although cellulose predominates, other constituents also influence the properties of these fibers (Table 12). Polymers of plant sugars other than glucose are collectively termed hemicellulose. Lignins appear in most fibers except cotton. Lignified fibers are identified by the phloroglucinol test (1,3,5-benzenetriol [108-73-6]) that is used to distinguish between mechanical and chemical wood pulp (⟶ Paper and Pulp).

Table 12. Composition (in %) of natural cellulose fibers at 10 % moisture content [57]

	Cotton	Jute	Flax	Hemp	Ramie	Sisal	Abaca
Cellulose	92.7	64.4	62.1	67.0	68.8	65.8	63.2
Hemicellulose	5.7	12.0	16.7	16.1	13.1	12.0	19.6
Pectin	0	0.2	1.8	0.8	1.9	0.8	0.5
Lignin	0	11.8	2.0	3.3	0.6	9.9	5.1
Water solubles	1.0	1.1	3.9	2.1	5.5	1.2	1.4
Wax	0.6	0.5	1.5	0.7	0.3	0.3	0.2

Useful fibers may be obtained from various plant parts:

- the stringy bast component of the stem — jute, flax, hemp, etc.
- leaves — agaves, notably sisal
- leaf petioles — abaca (manila)
- fruit — coconut fiber (coir)
- seed — cotton, kapok

Although few plants have hairy seeds, one genus, *Gossypium,* has been cultivated and bred for its fiber with such success that cotton now accounts for 90 % by value of all plant fibers and, if regenerated fibers are included, 78 % of all cellulosic fibers [58]. Figure 11 gives an idea of the worldwide cultivation of cotton and its economic importance relative to that of other plant fibers.

Figure 11. World production of natural cellulosic fibers, 1995

c) Cotton; j) Jute and kenaf; s) Sisal; f) Flax; a) Combined abaca and ramie

Each letter represents $ 400×10^6 production

2.1. Cotton

Table 13 describes the properties of the primary commercial species of cotton, of which American Upland (*Gossypium hirsutum*) is the most important, while Sea Island types account for only a few hundred bales annually. The species *G. hirsutum* has gained importance only in the last 200 years because of the lint's characteristically firm connection to the seed. This lint needed to be separated by hand until the invention of the saw-type gin — generally ascribed to ELI WHITNEY — improved the daily output of lint from 0.5 to 20 kg per person in 1 800, a rate now greatly exceeded.

Table 13. Properties of chief species of cotton

	G. barbadense	*G. hirsutum*	*G. herbaceum*

Common names	Egyptian American Pima	American Upland	Indian
Number of haploid chromosomes, designation	26, “new-world”	26, “new-world”	13, “old-world”
Usual ginning	roller	saw	roller or saw
Typical properties:			
Staple length, mm	35	26	16
Bundle strength, 3 mm gauge, g/tex*	30	24	24
Linear density, mtex*	120	200	350
Micronaire	3	4	7
Color	buff	white	tan

* 1 mtex = 1 mg/km

2.1.1. *Molecular Arrangement, Morphology, and Fine Structure*

Ginned cotton lint consists of ca. 91 % cellulose (dry mass). The remainder is made up of fibrous impurities, chiefly nitrogen compounds (proteins), wax, and pectins, which are found primarily on the fiber surface. (For the molecular structure and behavior of cellulose, see Chap. Cellulose.)

The unicellular cotton fibers grow on the seeds, whereby a tubular outer layer, the cuticle, is initially formed. When a normal fiber is fully developed, an empty cell channel, the lumen, which contains the residual dead protoplasm, remains.

The originally round fiber takes on the form of a flat or ribbon-like tube twisted in such a way as to have alternating S- and Z-shaped twists irregularly arranged along the length of the fiber. The cell wall of normal mature cotton is 2 – 5 µm thick. The fiber diameter is between 12 and 22 µm and is greatest (between 20 and 40 µm) at the base or seed end. Immature cotton has a thin wall, is only slightly twisted, and has a lumen filled with protoplasm. Prematurely withered (“dead”) fibers have an extremely thin cell wall (only ca. 0.5 µm thick) with conspicuous folds.

The cuticle is ca. 0.5 µm thick and covered with a layer of wax and pectins which form wrinkled overlapping rings when they are made to swell, e.g., with cuprammonium hydroxide. The primary wall, 0.5 – 1 µm thick, consisting of ca. 50 % cellulose with pectins, wax, and albumin, follows. The cuticle and primary wall account for ca. 3 % of the fiber's mass. The secondary wall consists of ca. 95 % cellulose and is arranged in numerous concentric layers. The layers denoted by S_1, S_2, and S_3 in Figure 5, consist of tightly packed parallel bundles of fibrils with helical coils along the fiber axis.

The fibrils are considerably less densely packed on the concave side, i.e., the side pushed into the interior of the fiber, than on the convex side, which has a more regular arrangement and a greater packing density [59]. This results from the collapsing of the fiber during its initial drying in the field. As a result, there are internal stresses, which determine the fiber's mechanical properties and, because of differing accessibility, its chemical properties.

The fibrils can be isolated by means of mechanical or chemical degradation (hydrolysis) of the fibers and can be identified with an electron microscope [60]. The major units are the macrofibrils with prevalent diameters of 300, 120, and 60 nm. They consist of microfibrils with a diameter of 10 – 40 nm and a length of 50 – 60 nm. The smallest fibril units are the elementary fibrils consisting of densely packed bundles of single linear polymeric cellulose chains with a diameter of 3.5 – 10 nm [61]. In the longitudinal direction the bundles of fibrils, connected by hydrogen bonds, alternate between highly organized (crystalline) and less-organized regions. This periodicity in the arrangement of the elementary fibrils reappears in the microfibrils in intervals of ca. 50 nm. Figure 4, shows a diagrammatic structural model of the microfibrils, which are constructed of elementary fibrils.

The review of ZAHN [62] summarized progress in elucidating the complex structure of the cotton fiber. Japanese research on the cultured algae *Valonia macrophysa* showed that the algae have regular cell walls. This indicates that the microfibrils are crystals containing 1 200 to 1 400 perfectly arranged cellulose chains [63], see Figure 12. Some of the earlier stress on the “amorphous” parts of the fiber or even of the molecular chains has shifted to assessing the pore-size distribution [64], because pores between 1 and 3 nm are most important for the uptake of dyes and many other finishes. The authors showed an increase in the proportion of pores in that range when cotton is boiled off, and a further increase when mercerized.

Figure 12. Suggested model for the ac projection of a cellulose crystal from the cell wall of *Valonia macrophysa*

No crystalline substructures exist, one single microfibril being one single crystal containing 1 200 – 1 400 perfectly arranged cellulose chains.

Attempts in recent decades to explain fiber strength, extensibility, and maturity in terms of molecular structure, crystallinity

and the distribution of degree of polymerization, whether using X-ray, near infrared, chemical, or other techniques that do not discriminate between primary and secondary walls, have commonly yielded only modest correlations, of limited practical value. There is increasing recognition of the difference between the properties of the primary wall, which forms first, and the secondary wall, which usually accounts for most of the fiber's mass [65].

One study of the secondary wall confirmed its close relationship with maturity. The development of the secondary wall was manipulated by changing temperature and light intensity to obtain vast differences in cell wall growth and secondary-wall development [66]. Comparative examination showed that the primary and secondary walls polymerize according to different mechanisms, with higher molecular mass, crystallinity, and crystallite size in the secondary (inner) wall [67].

The transverse dimensions of the cotton fiber are less obvious than in most other fibers, because most commercial measurements confound linear density with maturity and because of the peculiar and variable shapes; even within one boll on the plant, there is great variation in fiber development. Attempts to analyze measured fineness into linear density and maturity, by a variety of techniques, are becoming increasingly succesful. Automated image analysis, commonly longitudinal, but preferably of cross-sections, provides several measures that shed light on corresponding commercial properties:

Fiber thickness (the inappropriate term diameter is often used) is estimated from the Martin radius, such as the average of four diameters through the cross-section's center of gravity.

Linear density , in millitex or micrograms per meter, is directly proportional to the cell (i.e., total minus lumen) cross-sectional area, though calibration against known linear densities is needed at present.

Maturity is expressed as degree of thickening, which may be defined as the ratio of the above cross-sectional area to that of a circle having the same perimeter as the fiber.

Varietal fineness (UK: *Standard hair weight*) has defied reproducible measurement until recently. Each variety and species of cotton has a potential linear density reached when “fully” mature; experience with image analysis suggests that the average fiber perimeter is likely to distinguish best between varieties and to provide breeders with the best means of monitoring intrinsic fineness.

Convolutions with some sharp folds along the cotton fiber are shown longitudinally in Figure 13. Figure 14 is a cross-sectional view at the same magnification (1 100×), showing the lumens. These two figures indicate why cotton fibers are cohesive and easily spun in spite of their relative shortness.

Figure 13. Cotton fiber, longitudinal view, magnification 1 100×

Photomicrograph: Shirley Institute, Manchester, England

Figure 14. Cotton fiber, cross-sectional view, magnification 1 100×

Surface waxes are not strictly part of fiber structure, as they can easily be stripped off. Along with convolutions, they play a major part in cotton's processability, and may be regarded as a natural spin finish and the reason why cotton is the only fiber normally carded and spun without the addition of finishes to alter friction and cohesion.

2.1.2. *Properties*

Spinning Properties. The chief requirements for spinning textile fibers, and the extent to which they are met by cotton, are the following:

Fiber Length. Because a longer fiber can be spun into a better yarn with less twist, mills pay a substantial premium for “staple length.” This term is important, yet poorly defined. It describes a fiber that is longer than the mean but shorter than the longest fiber. Because of this premium, displacement of cotton by synthetic fibers has been greater at the long end of the cotton spectrum. This is because the price of synthetic staple fibers, which are cut or broken from continuous tow, is independent of fiber length. Cotton fibers vary considerably in length, even on individual seeds. Uniform lengths are coming into increasing demand.

Length Uniformity. Excessive numbers of short fibers increase processing waste and impair spinning. For the production of fine yarn, they must be removed by an expensive combing process.

Impurities and Grade. Cotton lint contains visible particles of leaf, seed, bark, and boll, known collectively as “trash.” Although grade is measured optically, either by the classifier or by colorimetry, it is largely a measure of the absence of trash in the cotton. Table 14 illustrates the correlation between grades and other characteristics. Examination of the last two columns shows that the price of cotton increases at ca. 3 times the rate that would be expected from its clean content. This demonstrates the importance of removing trash and dust early.

Table 14. Grades of American Upland cotton, white 1-in. staple length, 1984

Grade number	Traditional grade	Laboratory nonlint content, %	Cotton content after carding, %	Approximate commercial value, US cents/kg
1	good middling			170
2	strict middling	1.9	93.6	169
3	middling	2.3	93.0	167
4	strict low middling	3.1	91.8	163
5	low middling	4.3	90.2	156
6	strict good ordinary	5.5	89.0	135
7	good ordinary	7.8	85.0	121

The steep rise in value as impurities are removed shows, in common commercial grades, a price sensitivity of 3 : 1, i.e., each percentage increase in clean cotton content raises the unit price by 3 %. This provides an incentive for ginners to remove trash in rural areas before bales are shipped to the mills, where waste removal is more expensive. The controversial practice of lint cleaning degrades most fiber properties while maximizing the cotton grower's total revenue [68].

Traditional assessment of grade by classers includes a close look at “leaf”, because of the nuisance that it causes, especially to the extent that it is shattered into pepper trash in ginning and in the opening and carding processes at the mill. Colorimeters that earlier made assessment more reproducible failed to distinguish between lint that is generally discolored and white lint that contains abundant trash. This difficulty has been resolved by image analysis using digital trash meters, calibration of which enables reliable “gravimetric” estimation of trash content, measurement of particle size distribution, and conversion between laboratory and classers' measurements ([69] and Table 14).

Table 15. Effect of visible trash content on leaf grade (USDA, 1993)

Classer's leaf grade	Trash measurement, mass %
1	0.08
2	0.12
3	0.18
4	0.34
5	0.55
6	0.86
7	1.56

Further instrumental developments are approaching the classer's skill in distinguishing between different forms of trash, with bark and seed-coat fragments being the worst because, in different ways, they behave in processing much like discrete fibers, and are more likely to cause yarn breaks and unsightly fabric defects.

Color. Discoloration due to weather, excessive heat in drying at the gin, bacetria or insects may indicate sugary secretions or general degradation, and usually causes strength loss which results in price discounts. Colorimetry shows that grade and color correspond two-for-two with regard to reflectance and blueness/yellowness, but colorimetry also shows that greenness/redness has no influence on classification. Depending on the degree of yellowness appropriate for each grade, lint is classified as “white,” “light spotted,” “spotted,” “tinged,” or “yellow stained.” Excessively “white” cotton may exhibit bacterial damage within the fiber and is discounted as “gray.” In Egyptian cotton, a creamy tint is natural and considered desirable.

Micronaire. A complex measure of maturity (ca. one-third) and coarseness (ca. two-thirds), micronaire is determined by airflow instruments in micrograms per inch. The linear density or hair weight is, in fact, usually higher than this reading would indicate. Whatever the theoretical limitations of micronaire, it has proved to be a valid guide for assessing processing performance when the species and variety of the cotton — hence, the full potential of the micronaire — is known. American cottons are discounted if the micronaire is below 3.5, suggesting immaturity, or above 4.9, suggesting coarseness. Low maturity implies insufficient development of the secondary wall, with a tendency to form neps, more yarn breaks, and difficulty in dyeing.

Strength. Fiber strength is rarely a factor in the pricing of a bale of cotton. Not only is a stronger fiber likely to make a

stronger yarn and cause fewer processing problems, but as suggested by the trend in fabric weights since 1950, stronger fiber can be used more sparingly, thus making a lighter-weight fabric. Development of hybrid cottons, with strengths almost double that of Upland varieties, promises to widen the scope of cotton's applications.

Elongation and Stress – Strain Behavior. Cotton fiber stretches only ca. 7 % at break, less than most competitive fibers, but well above the 2 – 3 % of most of the other vegetable fibers described in this article. Cotton stretches in response to load in much the same way as polyester. This compatibility of mechanical properties enables the two fibers to be successfully blended and helps to explain why polyester/cotton is the most common fiber blend.

Cohesiveness. The spinning of yarn from discontinuous fibers requires a degree of surface cohesion. This is all the more important if, as in cotton, the fibers are short. Broken cotton yarns usually show evidence that only about half of the fibers have ruptured at the breaking point, while the other half have slipped. In cotton much of the cohesion is due to the natural convolutions in the ribbon-like fiber (see Chap. Cellulose), as can be shown by mercerization, which makes the fibers become rodlike and incapable of being spun. As yet, no commercial method for measuring this property in cotton is available.

Other Properties. *Moisture Uptake.* Cotton has a moisture regain of 8 % at 65 % relative humidity and of 15 % at saturation. Although this is exceeded by wool, jute, and rayon, the lack of a thick cuticle or sheath on the cotton fiber enables the fabric, when freed of natural waxes during finishing, to absorb moisture rapidly. Thus, cotton accounts for 94 % of the United States towel and diaper market [70], and although most printing is now done with pigments, cotton's rapid uptake of water-based dyes is an advantage to the finisher and printer. On the other hand, drying of cotton garments made of such water-retentive fibers after they have been washed adds to energy costs in comparison to those of the less-absorbent noncellulose fibers [71].

Secondary effects of moisture uptake are conspicuous in cotton because it is associated not only with the heat of sorption but with considerable *swelling.* In densely woven fabrics, such as canvas, this swelling blocks large pores, making the fabric impermeable to rain. At the same time, fabric thickening forces the tightly interlaced yarns into a more crimped configuration, which makes the fabric shrink. When the cotton dries, the restoring force is much weaker than the shrinking force, which leaves relaxation shrinkage.

2.1.3. *Production*

Cotton was originally a tropical perennial, but is now cultivated as a summer annual and with a ratoon crop in some tropical countries. It requires a longer growing season than any other annual crop. As an annual, it can be grown in cold-winter regions provided that there are at least ca. 1 200 degree-days above 15 °C during the growing season (one degree-day is recorded for each degree by which each daily mean temperature exceeds 15 °C). Thus, cotton is cultivated in latitudes as high as 45° N, with about 70 % of the world's cotton now being grown in temperate zones such as Uzbekistan, Northern China, and much of the American cotton belt (Fig. 11). The winter in these areas is cold enough to break the continuity of disease and insect problems.

Particularly in North America, the Mexican boll weevil has influenced the geography of cotton growing. Insects such as the heliothis, including the pink boll worm, and spider mite cause expensive problems. Honeydew that is secreted by aphids, whitefly, and other insects produces sticky cotton, which causes processing difficulties, especially when the fiber is passed through drawing rolls. In analysis, this “entomological” sugar must be distinguished from “metabolic” sugar produced by the maturing plant.

2.1.3.1. *Harvesting*

In developing countries, seed cotton is harvested by hand. It is pulled from the bolls, usually in two harvests, starting near the bottom of the plants as they ripen and open. Because strong winds may cause losses, stormproof varieties are planted in windy regions. These are short plants which resist lodging and have bolls that only partially open.

In high-wage countries, mechanical harvesting is predominant. Since this method is less discriminating than human fingers, the plants must first be defoliated either by frost or chemically. The seed cotton is still more contaminated than that obtained by hand. There is normally a single passage with the spindle harvester, as the bolls ripen. Some cottons, including all stormproof types, are harvested in a single operation by stripping the entire bolls, which gives a less-expensive, lower-grade lint. Stripping tends to remove strips of bark, which, because they are fibrous, are less easily removed than other impurities.

2.1.3.2. *Ginning*

Ginning is essentially the separation of lint from seed. Upland cotton is separated by rows of circular saws, which pass through slots that admit lint but not seed. Modern gins perform such functions as drying, blending, and cleaning seed cotton, lint cleaning, packing into bales of 220 kg and 0.5 m^3, invoicing, or marketing. Cottonseed, which accounts for ca. 65 % by weight and 15 % by value of the harvest, is sold separately.

When machine harvesting replaced hand harvesting, a more impure material was delivered to the gins, which resulted in the introduction of lint cleaners. Two passages through lint cleaners, at much higher speeds than in textile mills, restore the lint to the degree of purity that prevailed in the days of hand harvesting and maximize the growers' return. Lint cleaning is particularly useful for stripped cotton. However, it causes many fibers to break and invariably leads to more end breaks in spinning and, thus, a weaker yarn [72]. This weakness can usually not be detected at the fiber-testing stage.

2.1.3.3. *Byproducts*

Cottonseed directly from the gin is covered with short, coarse fibers called linters. These are cut off in one or two stages and used in wadding or as a raw material for cellulose plastics, such as ethyl cellulose. They were formerly an important raw material in rayon manufacture. (Seed for planting may be completely delinted by acid.)

The seed is then stripped of its hull, leaving a valuable “meat.” This is crushed, often with the help of solvent extraction, to

obtain the oil which may be purified for human and animal consumption. With an iodine value of 106, it is classified as a semidrying oil. Primary components are linoleic, oleic, and palmitic acid. The remaining meal, with a shelf life too short for retail trade, is used in commercial baking and as animal feed. The cotton seed contains gossypol, which is poisonous to nonruminants and must be removed for nonindustrial uses by hexane extraction.

2.1.3.4. *Processing*

On arrival at the mill, bales are selected for the desired yarn properties and blended, sometimes with synthetic fibers, in lots of about 30 bales. The first stages of processing greatly increase the bulk and remove much of the trash and dust. Further cleaning is achieved through carding and blending through drawing.

Generally, a roving is spun, which is then drawn and twisted into yarn by a ring and traveler during spinning. The yarn may be plied or finished before being made into a fabric. The newer process of rotor spinning, an open-end method, is excessively expensive for longer fibers, but cotton lends itself well to this technique, especially since rotor spinning is less sensitive to short or immature fibers than ring spinning.

Even though cotton yarn is easily knitted or woven, little is tufted into carpets. To withstand repeated abrasion during weaving, cotton warp yarn that has not been plied is treated with size. Increased speeds and stresses in weaving require yarn of uniform strength, which is largely true for rotor yarn.

2.1.3.5. *Finishing*

Because of its excellent stability in cool alkali and most bleaches, cotton is a particularly washable fiber, provided that shrinkage is controlled. Wet processing normally begins only after the yarn has been spun, usually after making the “gray” (unbleached) fabric.

Natural waxes inhibit the uptake of dye. The first stages are called “preparation,” i.e., for dyeing and printing, and include the following:

1. *Scouring.* Treatment in a hot detergent solution to remove natural impurities from the fiber surface as well as any oil and dirt from processing.
2. *Bleaching.* Removal of any remaining colored impurities through immersion into an oxidizing agent, usually cold hydrogen peroxide; this destroys trash particles or renders them invisible.
3. *Desizing.* Removal of sizes that were applied to the warp before weaving, either by acid hydrolysis or by the use of enzymes to remove natural starches.
4. *Mercerizing.* Originally a specialized process, mercerization is routinely used to increase dye uptake in cotton and polyester/cotton blends. It includes treatment with a cool, concentrated sodium hydroxide or ammonium hydroxide solution, which alters the crystalline structure from cellulose I to cellulose II, thereby improving the accessibility to water and, hence, to water-based dyes. If the yarns are under tension, the luster is enhanced and yarn strength increases by ca. 20 %. This process was formerly used to give cotton fabrics the appearance of the much more expensive silk, as well as to increase strength.

The fabric can then be dyed, usually by direct, vat, or reactive — occasionally basic, sulfur, or azoic — dyes. Pigment printing is popular, partly because of its excellent colorfastness, and because it can be applied to produce a solid shade in imitation of dyeing.

2.1.3.6. *Special Finishes*

Permanent Press. Because interchain bonds in cellulose are weak, cotton is easily deformed. Crease-resistant finishes, originally developed to reduce the severe wrinkling of rayon, are now widely applied to cotton. Several cross-linking agents, notably dimethylolethylenurea (1,3-bis(hydroxymethyl)-2-imidazolidinone [140-95-4]), are in use. These are applied to the fabric, dried, and then reacted by using heat (curing). The harsh texture that is thus imparted is mitigated by applying softeners. The introduction of polyester/treated cotton blends in 1964 proved successful, as the strength of the unaffected polyester enabled the application of resin to provide improved wrinkle resistance.

Flameproofing. Cellulose burns readily in air.

$$C_6H_{12}O_6 + 6\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O + \Delta H$$

Carbon monoxide is produced in confined spaces:

$$C_6H_{12}O_6 + 3\,O_2 \rightarrow 6\,CO + 6\,H_2O + \Delta H$$

In the presence of a Lewis acid, only charring occurs:

$$C_6H_{12}O_6 \rightarrow 6\,C + 6\,H_2O$$

Most flame retardants inhibit the first two reactions. They include simple soluble substances such as borax or alum and insoluble chemicals formed in the fiber by reaction, such as stannous oxychloride or antimony oxide.

Most introduce problems of handle, or “feel,” toxicity, or poor durability and have been largely replaced by a variety of organophosphorus compounds or by substitution with synthetic fibers in which an insoluble flame retardant is dispersed before the fiber emerges from the spinneret.

Shrinkproofing. In bottomweight fabrics (those > 140 g/m^2 and used for trousers, workwear, etc.), compressive shrinkage is used. A rubber blanket is moved in opposition to the fabric through the finishing machinery, so that the filling yarns are forced

together and the progressive shrinkage that would otherwise occur during repeated laundering is forestalled.

In topweight fabrics, such as shirtings and knits, satisfactory results are usually obtained as a side effect of the permanent-press resin.

Chemical Stonewashing. In many cotton-rich fabrics, especially in woven outerwear, a strong demand for moleskin and stonewashed finishes exists. Mild treatments include emersing, in which moderate abrasion of this fine fiber produces a soft finish. Increasingly, and especially when a “stonewashed” appearence is desired on denim, literal stonewashing is being superseded by controlled enzyme treatment with selected cellulases. Despite a weight loss of about 3 %, the finish does less damage to the fabric, and may be combined with other finishes such as crushing. It is applied to solvent-spun rayons of the Tencel type, the only type of regenerated cellulose fiber whose consumption is not in decline. Some celluloses are beginning to be used for the reduction or bleaching stage of vat dyeing, especially in denim.

2.2. Bast (Soft) Fibers

Plants with a stem containing a fibrous bast component may be commercially processed if the fiber yield and the ease of separation warrant commercial use [73]. The cross-section of the stem, shown in Figure 15, shows several undesired components which must be removed mechanically or chemically, a process that is frequently so odorous that the retting process must be carried out in less-populated regions.

Figure 15. Cross-section of plant stem with bast fiber

Although the process used varies according to the fiber, region, and available machinery, all bast fibers are generally subjected to the following processes after harvesting [73]:

mechanical or manual removal of seeds and leaves (rippling)
mechanical removal of bark (decortication)
biological removal of woody components through decomposition (retting)

At this stage the fiber, with some residual impurities, is usually baled and shipped to the mill for further processing.

The bast consists of long fiber bundles, which may be as long as the stem. These are made up of ultimate fibers containing lumens and are held together by woody gums; unlike most textile fibers, bast and leaf fibers are bundled. The elementary fibers, even though suitable for pulping, are too short for spinning, so that processing requires mechanical rupture of the bundles into manageable lengths. This is often achieved with a lubricant which softens the gums and allows the elementary particles to separate gently.

In addition to the fibers described here, other bast fibers of commercial importance include urena, sunn hemp, and kenaf.

2.3. Jute

Jute ranks second only to cotton among the natural cellulosic fibers. The net production of jute is greater than that of wool. Declining prices, about 40 ¢/kg in 1995, have reduced its importance since 1970. Since the early 19th century, jute has been intensively grown in the Ganges delta, and except for the substantial increase in jute cultivation in China since 1950, it has seldom been successfully cultivated anywhere else. Most jute-growing countries process jute to produce cloth locally, with only Bangladesh being a major exporter of the fiber [74].

Two varieties are used in commercial production. *Corchorus capsularis* (white jute) is tolerant of waterlogging and is grown on small delta farms subject to flooding during the summer monsoon. Harvesting of the 4-m stems with knives is sometimes done by divers. Good grades, such as Bangla (formerly Dacca) White A and B, are sometimes used for inexpensive apparel. Much bleached white jute in apparel weights appears in world markets as “hemp”. The two fibers are not easily distinguished, but jute is identified by turning yellow in sulfuric acid and iodine, not blue.

C. olitorius (tossa or upland jute) is grown on the wet slopes of India, Bangladesh, and Nepal. It is brown and contains noncellulosic impurities which cannot be completely bleached because of resultant excessive fiber damage. Some lowland areas produce “daisee” jute, which is gray or black because of iron salts in the soil.

The stems are retted in rivers, sometimes ponds, giving a fiber yield of only ca. 6 % (i.e., 18 t of “green” jute must be harvested to obtain 1 t of retted fiber). If the prices are high, the stumps (jute butts) are salvaged, though the middle of the stem produces the best fiber.

At the mill, the fiber undergoes blending and spreading with addition of ca. 5 % processing oil before carding. Because the fiber bundles are uneven in both length and diameter, individual yarns are irregular, giving the cloth its characteristic appearance. It is variously known as burlap, hessian, gunny, or sackcloth.

Jute has the shortcomings of cotton, with an even greater tendency to rot, but unlike cotton, it is usually too heavy and cheap to justify the cost of finishing treatments. It is normally not even scoured, formerly leaving the characteristic smell of old vegetable or whale oils on the cloth. Used mostly in carpet backing, sacks and bale wrapping, jute has been largely replaced in the developed world by bulk loading and the lighter, inexpensive polypropylene made from plastic film. Even organizations that advocate the consumption of their own natural fibers have urged the replacement of jute bales with synthetics. In primary carpet backing, polypropylene has also for the most part replaced jute, but it has the drawback of being thermoplastic. A roll

of carpet that has just been stored in a cold warehouse may, therefore, be too stiff to lay. Partly for this reason, jute is still common in the secondary backings which are applied to the underside, where its low extensibility helps stabilize the carpet.

2.4. Flax

Unlike cotton, flax (*Linum usitatissimum*) is grown less commonly for its fiber than for the seed, which is crushed to yield linseed oil. Over half of the world's flax is grown in countries that used to be centrally planned. With the sudden transition from subsidized farming to direct exposure to world markets, flax production for fiber has declined, e.g., from 2 000 to 800 t in two years in Estonia, but it remains a fashion fiber and is widely imitated.

The plant is much smaller than jute and is harvested by pulling out of the ground. It is retted on the ground ("dew" retting) or, increasingly, under controlled conditions in tanks. With a fiber yield of only ca. 11 %, an experimental process for retting in the field before harvest is receiving great attention.

At the mill, the fiber is processed more thoroughly than jute, often with "hackling," similar to combing, to separate long ("line") from short ("tow") fibers. About half of the linen yarns are moistened during spinning to lubricate the fiber ultimates which at about 10 mm length are twice as long as jute. Wet-spun flax yarn may be very fine and strong, but its low elasticity limits its ability to blend with other fibers.

The fact that flax has long been the standard against which other fibers have been measured, is expressed in terms such as "bed linen" and "table linen," even though flax fabrics are less durable than those of cotton or blends. The high absorbency of these fabrics destines it for use in towels but this is also combined with severe wrinkling and requires large amounts of crease-resistant resins.

2.5. Hemp

Hemp (Indian hemp) is rarely produced outside of the former Communist countries. The plant (*Cannabis sativa*) is widely cultivated for its leaves, known as marijuana, but the potential for salvaging the fiber in the stems has hardly been exploited. Yields per acre are lower than those for jute, which has similar properties. When grown for fiber, the plants are more closely spaced than for the drug crop, as leaf development is not needed. To distinguish the two uses and to encourage government support for hemp growing, many people have renamed the fiber "industrial hemp".

Because of restrictions on the drug, governments have discouraged production of hemp. World production of true hemp, insufficient to appear on the map (Fig. 11), is probably even lower than official statistics would indicate, because of widespread use of the misnomers "sisal hemp" and "manila hemp."

2.6. Leaf (Hard) Fibers

Fibers obtained from the leaves of plants such as *Yucca filamentosa* and agaves are extracted from the harvested, dried leaves — usually mechanically, since the leaves have spikes at the end and, in some species, along the sides.

These fibers are coarser, but more resistant to rot than the soft fibers and find application in cordage [75]. They have met with increasing competition from synthetic fibers. Common species are *Agave sisalana* (sisal) and *A. fourcroydes* (henequen).

Some banana trees, notably *Musa textilis,* have very fibrous leaf petioles. When separated from the rest of the leaf (tuxying), this abaca fiber can be used for high-quality ropes, often called manila. The natural tan color is sometimes imitated in other fibers through dyeing. Almost as elastic as cotton, manila ropes absorb shock loads better than most vegetable fibers.

2.7. Coir

The fibrous outer layer of the coconut, called coir, may be considered a seed fiber, like cotton, but is usually classified as a fruit fiber. The coarse fibers are commonly processed in India, Sri Lanka, and the West Indies and are woven into coverings for floors and playing surfaces.

2.8. Ramie

Ramie is a bast fiber taken from the stingless nettle, grown in the Philippines and the People's Republic of China. It rivals cotton in purity, whiteness, and strength. A minor fiber, it was omitted from the GATT multifiber agreement. Then it appeared abundantly, often in blends with cotton or polyester, in international trade, unhindered by quotas.

2.9. Economic Aspects

All of the natural cellulose fibers have been affected by the introduction of synthetic substitutes, first as regenerated cellulose (whose total worldwide production is less than one seventh that of cotton), later as fibers of fully synthetic polymers. Because rayon shares many of the problems of natural cellulose — and has a few of its own as well — most of the inroads into markets for plant fibers have been made by such fibers as polyester, nylon, and polypropylene. The replacement of jute and the leaf fibers by polypropylene has been particularly harsh. These newer fibers offer a higher strength : weight ratio than cellulose, as well as greater resistance to rot, mildew, burning, and wrinkling. On the other hand, some plant fibers, especially cotton, have maintained their position, world cotton production being at record levels. Of all the fibers used in apparel, cotton's share in all textiles has remained almost unchanged at near 50 % since 1974. Table 16 shows production trends.

Table 16. Proportions (in %) of the chief apparel-type fibers worldwide [76], [77]

Year	Cotton	Wool	Regenerated cellulose	Noncellulosic synthetics

1930	82	14	3	0
1940	75	12	12	0
1950	71	11	17	1
1960	67	10	17	5
1971	52	7	14	27
1984	49	5	9	37
1995	46	4	6	44

A good annual yield in most parts of the world is considered to be about 500 kg/ha (approximately, 1 kg/ha = 1 lb/acre) of cotton or 2 000 kg/ha of jute. Due to a growing world population, food production has been intensified and has caused some land to be diverted from the growth of cotton and jute to food crops. Table 17 shows production of the chief natural cellulose fibers. In interpreting these data, the increasing proportion of leaf fibers being made into pulp, rather than ropes or other textiles, should be kept in mind.

Table 17. World production of natural cellulose fibers (×10^3 t) [78], [79]

Year	Cotton	Jute	Flax	Hemp	Sisal	Abaca
1950	6 600	1 417	768	948		
1960	10 100	2 420	650	340		720
1971	11 600	3 446	670	269		821
1983	14 700	4 057	669	230	384	230
1994	18 900	3 530	610	120	380	76

Many of the fibers in this group, notably cotton and flax, are stronger when wet. Conversely, they are weak when warm and dry, a factor that played a part in reducing cotton's once-dominant position in tire cord.

2.10. Occupational Health

These fibers contain endotoxins which are shaken loose in processing if, as is usually done, the fibers are worked dry. Exposure to these airborne particles over decades may cause byssinosis in textile workers, especially in smokers. Regulations governing this problem [80] have caused profound changes in mills for processing cotton and have led to the redesign of machinery to reduce airborne dust. These changes are responsible for important secondary improvements in the processing behavior of cotton.

[Top of Page]

3. Regenerate Cellulose

Wilhelm Albrecht

Terms and Definitions. Man-made fibers are divided into two groups — cellulosics, and synthetics.

In both cases, the fibers are spun under conditions that are oriented to the end use in the form of continuous filaments. These filaments can be used as they are, textured, combined to heteroyarns, or cut into a staple of defined length.

In Germany, cellulose-based man-made fibers are produced according to DIN 60 001 from cellulose [81]. At present, the following three methods are used:

the viscose process — by far the most important (see Section Viscose Fibers)
the Lyocell process (see Section Lyocell Fibers)
the cuprammonium process (see Section Cuprammonium Fibers)
the acetate process (see ⟶ Cellulose Esters – Cellulose Xanthate)

Other production methods are discussed in Section Tentative Cellulose Fiber Production by Other Processes – Outlook.

While the first three of these processes result in regenerated cellulose fibers, the fourth gives cellulose ester fibers. The viscose process has been widely modified over time. One special kind of regenerated cellulose fibers is the so-called Modal fiber, which is available in two subgroups: the polynosics (= polymer non synthétique), and HWM fiber (= high wet modulus). In the Lyocell process, cellulose is regenerated from a solution in an organic solvent. Cellulose ester fibers are sub-divided into acetate and triacetate fibers (see ⟶ Cellulose Esters – Cellulose Acetate Fibers). Table 18 gives a listing of fiber designations according to ISO/TC 38.

Table 18. Fiber designation according to ISO/TC 38

Fiber	Generic name Code

Cuprammonium	cupro	CUP
Lyocell	lyocell	CLY
Modal	modal	CMD
Viscose	viscose	CV
Acetate	acetate	CA
Triacetate	triacetate	CTA

In addition, the main processing and application properties of the fibers are indicated by figures, descriptions, and short references such as:

number of single filaments
staple cut in mm
titer in dtex (1 dtex = 1 g/10 000 m)
bright (no dulling agent added)
dull/superdull (containing 0.3 – 4.0 % of a dulling agent, generally anatase)
hollow (hollow fibers)
ribbon (tapiform fibers)
crimped/high-crimped fibers (90 – 140 waves/ 100 mm)

Other descriptions may describe color, moisture retention, flammability, degree of optical brightening, suitability for medical applications, X-ray contrast, recommended uses, etc.

History. Regenerated cellulose fibers are the first artificial fibers ever made. Processes capable of dissolving the cellulose derived from wood or cotton linters were first discovered by SCHÖNBEIN (1845, nitrocellulose soluble in organic solvents), SCHWEIZER (1857, cellulose in cuprammonium solution), CROSS, BEVAN, BEADLE (1885, cellulose sulfidized in sodium hydroxide; 1894, cellulose triacetate in chloroform). The production of threads from cellulose (derivative) solutions goes back to AUDEMARS (1855), who drew filaments from cellulose nitrate submerged in alcohol ether, and SWAN (1883), who transformed nitrocellulose filaments into hydrated cellulose. Members of the Swan family used the threads, which were intended for the manufacture of light bulbs, for their craft work as well. SWAN called his discovery “artificial silk.” This early developmental work also set the trend for subsequent uses with regenerated cellulose fibers. In 1891, Count HILAIRE DE CHARDONNET built the first industrial plant for the production of artificial silk according to the nitro process in Besançon, France (daily output ca. 110 kg), and MAX FREMERY established the “Rheinische Glühlampenfabrik” for the production of cellulosic fibers suitable for carbon filament bulbs in Oberbruch (which developed into the Akzo Fibres Group). The spinning techniques were gradually improved: H. PAULY (1897) was granted a patent on a process in which “solutions of cellulose in copper oxide ammoniac are passed through fine holes into a liquid capable of decomposing these solutions” and published for the first time operable instructions. Other patents include TOPHAM's first spinning centrifuge (1900) and spin pump (1901); THIELE's stretch-spinning method for cuprammonium silk (1901); MÜLLER's spin bath for the viscose process (1905); and BOOS' continuous production of artificial silk (1906). A new phase was initiated in 1925, when H. STAUDINGER began describing macromolecules. The introduction of modifiers by COX in 1950 and the development of high-wet-strength fibers initiated by TACHIKAWA in 1951 again increased the variety of cellulosic man-mades. Commercial production of acetate fibers started in 1919; in 1955 they were joined by triacetate (see ⟶ Cellulose Esters). When during the 1960s synthetic fibers swept the textile market and water/air-pollution problems began darkening the image of cellulosic man-mades, they seemed doomed. However, after years of fierce competition, cellulosic fibers still maintain their characteristic place among fibers, doubtlessly aided by new developments in raw materials and in fiber manufacture [82]. The search for more ecological and more productive production methods led to the development of the Lyocell process in 1972 and in the course of time to a better adjustment of the raw material to improve the viscose process.

3.1. Viscose Fibers

3.1.1. *Principle of the Viscose Process*

The starting material for the production of filaments and staple fibers is pulp, mainly produced from wood and linters, but also from annual plants (⟶ Paper and Pulp). Since pulp fibers in their natural state are much too short to be spun into yarns, they are dissolved and regenerated in filament form. Part of these filaments is cut into fibers of the required staple length.

The spinnable solution is prepared by dissolving the raw material “pulp” in sodium hydroxide to obtain alkaline cellulose (first step), which is, if necessary, allowed to age (preripen) until a certain degree of depolymerization is reached (second step). Carbon disulfide is then added (third step). The resulting xanthate is dissolved in dilute sodium hydroxide (fourth step). With modern equipment, these four steps are combined into one.

Subsequent ripening (maturing) or a previously set degree of polymerization (DP) guarantee that the fiber can be perfectly spun and meet the requirements of the textile end use. During the process, the viscose is filtered, deaerated, and finally pressed through the holes of the spinnerets into the regeneration bath, where filaments are formed and drawn off at high speed (Fig. 16).

Figure 16. Flow diagram of viscose fiber production

a) Pulp; b) NaOH treatment and pressing; c) Shredding, aging, if necessary; d) Carbon disulfide treatment, xanthate crumbs; e) Dissolving xanthate in NaOH, viscose maturing; deaeration, filtration; f) Filament yarn; g) Staple

Fiber properties can be widely varied by changing the processing conditions, such as the compositions of the viscose and the regeneration bath, chemical additives, and modified spinning technology (spinning bath temperature and spinning speed, drawing ratio and geometry, number and nature of the baths, etc.) [86-90].

3.1.2. *Viscose Preparation*

For textile filaments and staple, the preferred raw material is bleached wood pulp with an α-cellulose content of 89 – 93 %; it comes in sheets, rolls, or crumbs. High-tenacity filament yarns and modal fibers require even higher grades of pulp (≧ 94 % α-cellulose). Cotton linters are used mainly in cotton-producing countries.

The cellulose must fulfill certain requirements with regard to processibility (unit weight, swelling behavior, hemicellulose content, inorganic substances, degree of polymerization (DP)) and the properties of the resulting fibers. Many efforts were made to “activate” cellulose by thermal treatment, radiation, introduction of spacers, and surfactants [82]. It has been found that a suitable irradiation with β-rays is the most useful method [83].

Alkalization. When exposed to sodium hydroxide of 20 % or more, the pulp absorbs water and alkali, releases heat (ca. 12 kJ/mol anhydroglucose), and loosens the cellulose lattice. This results in sodium cellulose I (Section Chemical Properties), most of which changes into cellulose II during regeneration.

Although alkaline cellulose is an important intermediate product in cotton mercerization and in the preparation of viscose as well as various cellulose ethers, its nature has not yet been fully explored. Cotton mercerization is primarily intended to change the interfibril structure, which is also possible with other swelling agents. Alkaline treatment during viscose preparation is, apart from opening the molecular structure, aimed at transforming as much cellulose as possible into sodium cellulose I. This explains why several different definitions are suggested for the alkaline phase of the cellulose, such as “pseudostoichiometric combination $(C_6H_{10}O_5) \cdot (NaOH) \cdot (H_2O)_{3-5}$,” or “a more or less loose addition of water molecules and hydroxyl groups of the cellulose to an Na^+OH^- dipole.” Besides, some authors mention mesomerizable onium compounds with a cation of limited mobility as well as the fact that some of the cellulose has the form of a hydrated alcoholate Cell-$O^-Na^+ \cdot H^+OH^-$ attached to it [97-99].

Commercial treatment of the pulp starts with the addition of 18 – 22 % sodium hydroxide of 17 – 45 °C. Sometimes depolymerization catalysts such as manganese salts are added. An alkaline cellulose content of ca. 30 % is obtained by pressing. If necessary, the alkaline cellulose is shredded and left to age (generally a continuous process). At this stage, it is important to control the temperature and the surface of the crumbs must not be allowed to dry out. This is particularly important in shortened ripening methods. The degree of polymerization for normal textile fibers is set at ca. 300 and for high-tenacity yarns at ca. 450 and higher.

It has long been known that during the third stage of the viscose process, hemicellulose readily attracts the carbon disulfide, and numerous efforts have been made to reduce the hemicellulose content of the alkaline cellulose. One possibility would be tandem steeping, i.e., two alkaline treatments. The first serves to wash out part of the hemicellulose that is already present in pulp and is formed during swelling and alkaline cellulose formation. After the second alkaline treatment the alkaline cellulose has a low hemicellulose content and distinctly less carbon disulfide is needed for xanthation (20 – 30 % less).

The composition and condition of the alkaline cellulose are governing factors for its processing properties (grinding, preaging, xanthation, filtration). Therefore, it is necessary to check the temperature and the composition of the alkaline solution (hemicellulose, sodium carbonate, alkaline- earth metals, and heavy-metal ions). Sodium carbonate is generally present in percentages between 0.09 and 0.3 %. Higher concentrations may create difficulties in viscose filtration. Varying heavy-metal ion concentrations cause differences in the depolymerization reactions during ripening [100], [101].

Shredding. If the alkaline treatment starts with pulp sheets or rolls, it is followed by shredding. At the same time, the alkaline viscose is adjusted to the ripening temperature. Higher temperatures (up to 45 °C) accelerate the process, lower temperatures (around 20 °C) prolong it. Shredded alkaline cellulose consists of white crumbs. The density by volume is held constant.

Preripening. The pulp and, hence, the alkaline cellulose now usually have a degree of polymerization (DP) which is much higher than desired for fiber formation. The delicate viscose process requires a viscose with an optimal combination of concentration and viscosity. Therefore, the DP must be reduced to ca. 300 (for regular fibers) or 450 or slightly higher (for high-tenacity fibers). The preferred method is to store the alkaline cellulose for a certain period of time at 20 – 45 °C. Care must be taken to avoid drying of the crumbs, which would result in carbonate formation, particularly at higher temperatures. For this reason, the alkaline cellulose is stored in closed containers or is constantly agitated (in continuous operations). Depolymerization is an exothermal process and can be accelerated by suitable catalysts. The results depend on such factors as time, temperature, the nature of the pulp, and the composition of the alkaline cellulose (NaOH, H_2O, hemicellulose, and heavy metals) [102]. This ripening process is either discontinuous (i.e., in containers) or continuous (i.e., in special cabinets

provided with conveyor belts or in rotating drums).

It is generally believed that cellulose fiber producers should themselves adjust the preferred DP by ripening the alkaline cellulose. Currently, this is the most economical method. This principle is questionable, since new studies have been published and attractive uses for byproducts from pulp production are thinkable. Preripening can be avoided if pulp is used as feed material, whose degree of polymerization has been adjusted to the desired level by irradiation with β-rays. This treatment also leads to a favorable leveling of the DP.

Xanthation. This term means treatment with carbon disulfide with which the alkaline cellulose reacts and generates heat. The reaction is very rapid and begins on the outer surface of the crumbs — hemicellulose included — and slowly proceeds into the crystalline structure. This homogenating process continues until the viscose is ready for spinning. In commercial production, based on unirradiated pulp an average substitution degree of 0.5 – 0.6 is obtained, reflecting a ϒ-value (number of xanthate groups per 100 glucose units) of 50 – 60. ϒ-Values of ca. 50 are sufficient for a readily filterable viscose free from fibrous material. High-tenacity yarns require higher ϒ-values. Under special conditions, it is even possible to obtain ϒ-values of up to 300. Xanthation is not uniformly distributed over the cellulose chain, and even with a substitution degree of 1, not all of the glucose groups will have one substituent, let alone one in a specific place. Alkaline cellulose made of irradiated pulp can be reacted with distinctly less carbon disulfide to yield a good soluble xanthate. In practical operation ϒ-values of 30 – 35 for textile viscose fibers are used.

Table 19 shows the distribution of the xanthate groups over C-2, C-3, and C-6. There are indications that the speed with which the primary and secondary xanthates are formed and destroyed must be different. The hydroxyl groups in position C-2 are the fastest to react with xanthate, but are less stable than those attached to primary C-6 hydroxyl groups.

Table 19. Distribution of xanthate groups over C-2, C-3, and C-6, in % [103-105]

Hydroxyl groups occupied	Acc. to [103]	Acc. to [104]	Acc. to [105]	
			fresh	ripened viscose
			ϒ = 60	ϒ ≪ 49
C-2	43	38	a	b
C-3	20	28	a	b
C-6	37	34	31	60 – 100

[a] ∑ (C-2 + C-3) = 69 %;
[b] ∑ (C-2 + C-3) = 0 – 40 %

Xanthation speed depends on temperature, the condition and composition of the alkaline cellulose, the amount of carbon disulfide added, and the pressure of the carbon disulfide vapors formed during the process [103-106]. Pulp that has been adjusted to a desired DP by β-irradiation shows a more favorable behavior during xanthation than untreated pulp because of its narrower DP distribution. A much lesser amount of carbon disulfide is required for reaction and the reaction time is reduced. In addition, the spinning properties of the viscose obtained are even improved, when certain limiting values are complied with.

Side Reactions. Xanthation of alkaline cellulose is accompanied by a great number of side reactions. They are responsible for the characteristic orange color of the xanthate and the viscose made from it.

Carbon Disulfide. Depending on the type of fiber and the alkaline process used, between 150 and 400 kg of carbon disulfide is needed to produce 1000 kg of fiber. CS_2 is a clear, colorless liquid that is to distilled at 46 – 47 °C up to 98.5 %; it should contain < 5 ppm of hydrogen sulfide and be free from carbonyl sulfide and acid. The nonvolatile residue content should be less than 0.01 %, and the density should be 1.26 – 1.27 g/cm^3.

Process Techniques. Older equipment may still contain hexagonal drums (heated jacket, teflon coated, vacuum tight). They are filled with alkaline cellulose with adjusted DP and evacuated. The required amount of CS_2 is added via the perforated axle of the drum (15 – 55 %, in the classic process 28 – 35 %). Pressure develops and replaces the vacuum; gradual normalization is aided by cooling. Xanthation takes 1.5 – 2.5 h, after which nitrogen is injected; the remaining carbon disulfide is removed and the orange xanthate crumbs are dumped into the dissolving tank. This early process was work-intensive and exposed the workers to noxious carbon disulfide vapors. During the 1950s, deep-reaching changes took place. Kneaders were introduced which held much larger quantities of alkaline cellulose for xanthation and allowed the first phase of xanthate dissolution to take place. The kneaders were followed by automatic sulfidizing and dissolving equipment.

Processes involving carbon disulfide are dangerous. Sparks may trigger explosions. Safety instructions must be carefully observed.

Viscose Solution. The xanthate crumbs are dissolved in sodium hydroxide either in batches or continuously to give a sticky substance; hence, the name viscose. Dissolution is accelerated by stirring and trituration. The honey-colored viscose contains 7 – 12 % cellulose and 5 – 8 % caustic, as well as various sulfur compounds and carbonate. Viscosity varies from 3.5 to over 10 Pa · s and depends on the concentration of the xanthate, the degree of polymerization of the cellulose, the degree of dissolution, which in turn is a function of dispersion, the degree of substitution and its distribution, and on the purity

and concentration of the dissolving sodium hydroxide.

To avoid such common interferences as short fibers and gels, certain chemical auxiliaries are added directly either to the pulp or to the viscose. These auxiliaries are surfactants such as fatty amines or polyglycol compounds in fractions of 1 ppm of viscose.

Maturing. Maturing is another delay period, during which sulfidation continues and substitution becomes more uniform. At the same time, the ϒ-value is reduced and the amount of byproducts increased, while the ability of the viscose to coagulate also increases (chemocolloidal maturity).

Chemocolloidal maturity can be described by the Hottenroth index (°Ho). It is determined by thorough mixing of 20 g of viscose 3 times with 10 mL of distilled water. A 10 % solution of ammonium chloride is added at 20 °C. When “maturity titration” is completed, the viscose changes into a semisolid gel which should adhere to an horizontal stick for at least 20 s. The Hottenroth index corresponds with the number of cubic centimeters of ammonium chloride required to obtain that result. At the start of the maturing process, the Hottenroth index reaches a maximum [107].

This manual maturity test can be easily automated. With the help of suitable apparatus, the maturing process of the viscose can be made much more uniform [108].

The decomposition speed of the sodium xanthate depends on the temperature and concentration of the sodium hydroxide, cellulose, and carbon disulfide [109]. The nature of the reaction has not yet been fully determined.

With older equipment, the maturing process at ca. 18 °C takes several days (50 – 80 h). It can be adjusted to the type of fiber to be spun and the spinning method to be used. Maturing is accompanied by filtration and deaeration.

These three operations have been accelerated and automated by increasing the viscose temperature, the development of various kinds of filters, and the introduction of vacuum evaporation.

3.1.3. *Viscose Fiber Spinning*

Fiber formation, i.e., regeneration of the cellulose from the viscose with the help of the spin bath and treatment outside the spin bath, includes coagulation of the viscose (sol – gel), deswelling of the filaments, regeneration of the cellulose, neutralization, and stretching of the yarn. The chronological sequence of these steps (which overlap and run parallel) determines the structure and, hence, the properties of the resulting fibers.

Composition and Effect of the Spin Bath. The formation of the thread in the sulfuric acid bath involves a number of chemical reactions. The most important is the decomposition of xanthate into cellulose and carbon disulfide. Besides, the thiocarbonates formed in side reactions during sulfidation and maturation disintegrate. These two basic reactions can be described in a simplified form as follows:

$$2\,\text{Cellulose} - \text{O} - \text{CSSNa} + \text{H}_2\text{SO}_4 \rightarrow 2\,\text{Cellulose} - \text{OH} + 2\,\text{CS}_2 + \text{Na}_2\text{SO}_4$$

$$\text{Na}_2\text{CS}_3{}^* + \text{H}_2\text{SO}_4 \rightarrow \text{Na}_2\text{SO}_4 + \text{H}_2\text{S} + \text{CS}_2$$

* Representative for a number of inorganic thiocompounds.

In addition, carbon dioxide is formed when the caustic lye reacts with the carbon disulfide, and finally, colloidal sulfur is released.

Sulfates — mainly Na_2SO_4, but also $MgSO_4$ and rarely $(NH_4)_2SO_4$ — allow the viscose to coagulate, i.e., macromolecules and associates join into larger aggregates; acids alone initiate rapid disintegration of the viscose, and sulfuric acid of higher concentrations than 55 % gives high-tenacity, low-elongation Lilienfeld Silk at low bath temperatures.

The composition of the spin bath is adjusted to the composition of the viscose and the type of fiber to be spun (i.e., titer, tenacity, and crimp). Spin bath temperature, spinning speed, the amount of viscose injected, and the construction of the spinneret are further factors. In general, a spin bath will contain 7 – 12 % sulfuric acid, 12 – 24 % sodium sulfate, and 0.5 – 3 % zinc sulfate. In exceptional cases, part of the sodium and zinc sulfate can be replaced by magnesium sulfate (ca. 5 %) so that the swelling of the filament is reduced before winding.

In practical spinning operations, the matured viscose from the tank is injected by precision pumps through fabric filters inside the spinneret support and then through the holes of the spinneret. The body of the spinnerets is made of gold or platinum alloys, with or without rhodium, or of platinum/iridium alloys. Some tantalum and glass spinnerets can still be found. However, since it became clear that the spinnerets are a very important machine part in viscose fiber production, more attention is being paid to high quality. This also includes the finish and form of the spinning holes. Seen in the flow direction, these holes have a conical inlet followed by a cylindrical channel. The cone is about double the length of the channel, but must be adjusted to the thickness of the plate. Depending on the intended fibers and their thickness, the channels have a diameter between 50 and 250 µm. In filament yarn spinning, the number of holes is equal to the desired number of single filaments in the yarn (for example from 18 to 1 000); in staple fiber production, it may surpass 90 000. Spinnerets of this kind are composed of several smaller spinnerets combined into one spinning point. For relatively wide ribbon fibers spinnerets with oblong holes are employed.

When the viscose emerges from the submerged spinneret and enters the spin bath, it begins to solidify. Special “marching-off” devices ensure regeneration of the cellulose in filament form and completion of cellulose regeneration. Spinning and pumping speed are precisely adjusted. Filament yarns of 100 dtex are wound at up to 160 m/min; filament tow for staple production is spun at between 35 and 120 m/min, depending on the fiber type and the number of filaments.

The regenerated cellulose fibers gain more tenacity and less elongation with a higher final degree of orientation. The process is supported by keeping sulfuric acid in the spin bath at a minimum, by adding certain chemicals, and by increasing the zinc content to decelerate the decomposition of the xanthate. Polynosic fibers are spun into a low-temperature bath at lower speeds.

Depending on the composition of the viscose, the spin bath and the flow diagram of the viscose leaving the cylindrical part of the holes starts filament formation in differently structured layers. This is due to the differences in the diffusion speeds of the hydrogen and zinc ions and the reversal of the acceleration diagram of the flowing viscose. On their way out, the degradation products that result from reaction with the faster hydrogen ions meet the slower zinc ions, with which they combine and precipitate ($ZnCS_3$ and ZnS_2). At the same time, two distinct layers are formed in the fiber; the outer one being less-swollen zinc xanthate and the inner one highly swollen sodium xanthate (skin/core). Both layers are differently structured, e.g., regarding the size and total volume of cavities [110-115]. The outer layer differs from the core in the following respects:

smaller crystallites (sometimes cellulose IV residues)
increased strength and elongation
greater resistance to fatigue
less lateral order and density by volume
lower refractory index
lower wet modulus
less accessible to large low-polar molecules
lower defibrillating tendency

The relation between skin and core is about 1 : 3 in standard viscose fibers and 1 : 0.5 or less in high-tenacity fibers.

The cross-sectional shape of the viscose fibers (see Fig. 20) depends on spinning conditions (deswelling, shrinking, drawing, and drying). Addition of varying amounts of zinc sulfate, adjustment of viscose and spin bath composition, variation in maturity, and high byproduct sulfur content may increase the thickness of the skin to almost full fiber thickness (see Section Fiber Types). The amount of crystalline matter (28 – 50 %) and degree of orientation, lateral order and size of the crystallites are determined by stretching the filaments at different formation points [90]. In standard viscose yarn production, stretching occurs late in the decomposition phase; high-tenacity yarns are stretched in a less decomposed condition. Stretching of the plastic gel filaments has no measurable effect.

Stretching is generally done in several steps. Little stretch is applied between the spinneret and marching-off device, while a higher stretch is exerted between the drawing rolls on the spinning machine. High-tenacity fibers are drawn on separate roller arrangements. Continuous stretching between rolls mounted at an angle or on godets does not necessarily seem more advantageous than sectional drawing. The total amount of stretch applied ranges between 20 % for standard fibers and up to 150 % for high-tenacity fibers [116-120].

The sulfuric acid for the coagulation bath (ca. 1 kg of 96 % H_2SO_4/kg of fiber) should be highly concentrated (iron storing tanks), of high purity (colorless and free of odor), and free from arsenic. The Fe content should be < 100 ppm, and Cu content < 1 ppm.

The zinc sulfate should not present dispensing problems (hydrated crystals or zinc oxide). Purity requirements are as follows: Cu < 10 ppm, Pb < 30 ppm, Fe/Mn/Ca < 100 ppm each, Mg < 500 ppm, chloride < 0.3 %.

During the spinning process, sodium sulfate is produced in the form of Glauber's salt ($Na_2SO_4 \cdot 10\ H_2O$, ca. 1.2 kg/kg of fiber). It is generally calcined and sold to the glass and detergent industries.

Processing water should be soft and low in heavy metals (total and carbonate hardness ≈ 0, Fe < 0.05 mg/L, Mn < 0.03 mg/L, permanganate index ca. 2.5 mg/L).

Surfactant auxiliaries (modifiers, additions to the spin bath, aftertreatment agents, and finishes) are used at various stages of the viscose process. They must be selected for compatibility. Ethylene oxide additives with or without nitrogen and polyalkylene glycols will, for example, promote xanthation, dispersion, and alkalization, hence, the filter properties and spinnability. Surfactants may be added to the pulp or the alkaline cellulose. For high-tenacity fibers, special additives are used as modifiers [121], [122]. Spin bath additions make for a clearer spin bath and reduce deposits on the spinnerets.

Recovery of Chemicals. The steeping sodium hydroxide pressed from the alkaline cellulose is partially cleaned by dialysis and reused. It dissolves the cellulose xanthate and serves as a washing bath for the regenerated fibers.

Spin bath solution is filtered, vacuum-deaerated (removal of H_2S), reduced, and reused. The Glauber's salt generated in the process is removed and calcined.

The carbon disulfide released during the fiber-making process is collected, freed from hydrogen sulfide (if any), and adsorbed on activated carbon. In this way, up to 70 % of the initial amount can be recovered and distilled for reuse.

Part of the hydrogen sulfide is changed into sodium sulfide (for desulfation baths) and oxidized to pure sulfur or sulfuric acid.

3.1.4. *Fiber Types*

Regular Fibers. Classic spinnable xanthate solution (7 – 10 % cellulose, 5 – 7 % sodium hydroxide, 25 – 35 % carbon disulfide, maturity 10 – 15 °Ho) is spun into an acid salt bath (≧ 80 g/L sulfuric acid, 150 – 300 g/L sodium sulfate, 10 – 20 g/L zinc sulfate) at 45 – 55 °C. The first regeneration trough is 20 – 80 cm long and the fibers are drawn off at a speed of

80 – 160 m/min. The prestretched filaments are washed with cold and hot water and collected on rolls, spools, or cakes for deacidification. Other treatments have the purpose of removing sulfur, bleaching, application of lubricant, and drying.

The process can also be arranged for continuous operation by using wide machines for collective treatment of yarn sheets or single filament treatment. Collective treatment gives larger throughput, more uniform quality, and larger bobbins. Insulation of the machines is, however, more difficult than in single filament treatment, which is less productive, supplies smaller bobbins, and can result in differences within the yarns (between spinning points, as well as over the length of the threads). The threads are normally spun by immersing the spinnerets into the spin bath and drawing off the filaments upwards. This involves the formation of a “jacket” of varying size between the filaments and around the fiber bundle. The size of this jacket depends on the take-off speed. This jacket, which is stripped off, limits the production speed. That is why more recent production systems involve spinning from top to bottom, similar to the cupro process. In principle, a production speed of ca. 350 m/min is feasible for fine single filaments, this speed is currently limited by the drying operation.

Regular viscose fibers have a rather low wet modulus; wet strength is about 60 % of dry strength, and moisture absorption is about 100 %, this is 2.5 times higher than that of cotton. These facts needed to be considered in textile processing and led to the search for fibers with a higher wet modulus, higher wet strength, and reduced moisture absorption. The successful result of these efforts was the so-called modal fibers (staple) and high-tenacity (industrial) filaments.

Crimped viscose fibers are turned into functional fabrics either alone or in blends with wool, polyester, or acrylics. They are based on a relatively “unripe” grade of viscose (15 – 20 °Ho). Xanthation uses the same amount of carbon disulfide as previously described, but spinning conditions are different. The spin bath is less acid, whereas the second bath has a higher acid content (up to 30 g/L sulfuric acid). When the filament passes the second bath, it is stretched to a higher degree; the initial skin breaks up under the tension, and a new irregular skin is formed. This in turn creates tensions over the cross-section of the yarn which deform the fiber into waves and crimps (Fig. 17). Their number per 100 mm can be widely varied, but processing requirements set certain limits (in a 3-dtex staple fiber, the crimp varies with fiber type from 100 to 125 waves/100 mm) [123].

Figure 17. Skin – core structure of a crimped viscose fiber

In cellulose fibers, the crimp durability is inferior to the crimp in synthetic fibers, particularly in the wet state.

Industrial (High-Tenacity) Yarns. When filaments are spun from top-quality viscose (ca. 7.5 % cellulose from high-quality pulp, 7 % sodium hydroxide, 38 – 40 % carbon disulfide) and highly stretched during regeneration (up to 100 %), the result is a *high-tenacity filament* or *cord yarn.*

Supercord yarns, i.e., fibers with a homogeneous full-skin cross-sectional structure, require a starting pulp with a high α-cellulose content and a uniformly high degree of polymerization. Viscose ripening is lowered, and carbon disulfide content is increased. The spin bath consists of less sulfuric acid, but a larger amount of zinc sulfate. Spinning speed is reduced, no stretch is applied in the regeneration bath, but very high stretch ($\gg$ 100 %) is applied in the second bath. Modifiers are added to the viscose and bath, e.g., monoamines, polyethylene glycols, oxyethylated ammonium derivatives, and polyglycols condensed with various organic radicals.

Extra-high-modulus fibers (EHM) are obtained by adding formaldehyde to the spin bath, sometimes also to the viscose itself. This will further increase fiber strength and reduce elongation to < 10 %. The fibers show a certain tendency to split into fibrids.

Medium- and high-wet-strength viscose staple is made under much the same conditions as cord and supercord yarns. Compared to the viscose used as regular staple, the viscose for higher tenacity fibers contains more sodium hydroxide, has a lower degree of maturity, and is spun into a regeneration bath containing up to 40 g/L zinc sulfate and more. Spinning speed is lower, but the drawing ratio higher. To ensure optimal uniformity of coagulation and decomposition of the many thousands of single filaments, it is not unusual to use a tube arrangement as in supercord production. This also allows a certain reduction in the amount of spin bath required per spinning point.

Modal Fibers. Modal fibers are also spun from viscose and come in two varieties: *polynosics* and *HWM* (*high wet modulus*). Both are based on higher quality viscose than regular staple (6 – 8 % cellulose, 6.5 – 8.5 % sodium hydroxide, 40 – 50 % carbon disulfide; small amounts of a modifier and some zinc may also be added; the viscose for polynosics can also contain traces of formaldehyde). Modal fibers — they are always cut to staple lengths — are spun into a slightly acid bath of low temperature and with a strong coagulating effect (20 – 30 g/L sulfuric acid, $\geqq$ 25 g/L sodium sulfate, < 10 g/L zinc sulfate), which is sometimes difficult to recover. The stretch applied in the second bath may exceed 150 %.

HWM fibers can generally be spun on conventional viscose spinning equipment, while polynosics require essential machine modifications. If formaldehyde is added, special precautions in spin bath treatment are necessary.

Cellulose xanthate for polynosics contains relatively long molecules and is spun at lower speeds than regular viscose. Due to the lower acidity of the bath, the number of nuclei formed when the mixture enters the bath is reduced. They grow into long, tapiform crystallites which lend themselves to easy orientation. The result is a network of long, solid crystalline bundles in whose inner regions even the noncrystalline matter shows a certain degree of orientation and, hence, resistance to penetration. As regeneration speed is also reduced, the nascent filaments remain deformable for a longer time, which allows

absorption at higher drawing rates than with HWM fibers. This gives almost complete orientation of the cellulose molecules in the direction of the fiber axis.

In polynosic fibers, the cellulose crystallites are made up of alkali-resistant cellulose II. This is the only type of fiber made from cellulose xanthate which displays the fine fibrils seen in cotton.

In HWM fibers spun in the presence of modifiers, the length of the crystallites and their orientation are somewhat less than those with the polynosics. Moreover, the crystallites contain not only cellulose II, but also orthorhombic cellulose IV [99, p. 90]. Sodium lye of concentrations greater than 4 % causes the lattice of cellulose IV to change into cellulose II. If not subjected to tension during this process, the cellulose II remains unoriented and acts as an instable disturbance within the pattern of ordered macromolecules [124], [125]. This in turn jeopardizes the mercerizing properties and gives a higher elongation than found in polynosics. Practical experience has shown that dry elongation of more than 15 % can result in fiber damage during mercerization.

Addition of formaldehyde or formaldehyde-releasing compounds in the course of the polynosic fiber spinning process will promote gel orientation. Methylene chains will attach to the cellulose chains and strengthen the network to an extent that sometimes allows drawing ratios of 500 – 600 %, a mixed blessing.

3.1.5. *Modified Viscose Fibers*

Using weakly acidic baths (ca. 15 g/L sulfuric acid) containing more than 100 g/L ammonium sulfate, it is possible to spin so-called coagulation fibers (see Section Fiber Properties) from ripe viscose (< 10 °Ho). They have a round cross-section and a scarred surface, are easy to dye, and offer good dimensional stability. Their structure results in reduced strength and, thus, makes production of fine fibers (< 3 dtex) difficult.

With the help of inorganic pigments which are added to the viscose, colorfast spun-dyed fibers are produced. Addition of some 40 % barium sulfate (based on the weight of the fiber substance) gives the fibers X-ray contrast mainly required for medical textiles.

Optical brighteners added to the viscose give a brilliant white. These fibers, however, should not be used for medical purposes. It is also possible to include flame retardants (halogen, phosphorus, and nitrogen compounds). Certain sequestering agents may be used to modify the dye affinity of the fiber so that it accepts acid dyes. Blends of regular and acid-dyeing fibers then allow attractive differential dyeing.

The wet spinning process is well-suited for the addition of substances to the spinning solution. In connection with the viscose process, the additives must, however, be selected for resistance to the strongly alkaline and acid process conditions.

Another fiber modification involves *grafting.* Grafting can be carried out during fiber production as well as in textile finishing. In process grafting, the method should not require extremely drastic changes in the normal schedule and avoid reduction of the spinning speed, which is usually very difficult to manage [126-129].

Depending on the type of monomer or polymer to be grafted (e.g., styrene or acrylonitrile) the grafting process can be initiated by ions ($Ce^{4+/3+}$, $Fe^{3+/2+}$) or free radicals. It is possible to produce radicals on the cellulose by UV radiation in the presence of photosensitive agents [130]. In addition, high-energy rays from γ-ray sources and electron accelerators are used [131-133]. These processes differ in the chronological order of the monomer bath, drying, and source of radiation. The choice of the method is a function of the desired effect, process economics, and the properties of the monomer and polymer. The radiation dose reaches an approximate maximum of 10 J/kg. Yield is affected by the monomer concentration, type of solvent, swelling degree of the textile, and the radiation dose [134]. From an economic standpoint, low-energy radiation, e.g., argon plasma, which as a highly ionized gas emits positive ions and electrons, may also have importance in the future [135].

Grafted fibers are still in a very early phase of commercial use in spite of years of strenuous research efforts. On a pilot scale, some carpet fibers (CV/PAC) as well as flame-retardant, bacteria-resistant, water- and oil-repellent fibers have been spun in the Russia; also included in this research program were acid-protective, ion- and electron-exchanging, complex-forming, antimicrobic, and hemostatic fibers [129].

For more information on fiber modification, ⟶ Textile Auxiliaries.

3.1.6. *Fiber Properties*

Structure and Properties. As with cotton, the physical properties and the reaction of the fibers to chemical treatment is governed by the fiber buildup – the macrostructure (morphology) and the fine structure. Compared with cotton, the structure of regenerated cellulose fibers is much simpler [136], [137]. Unlike natural cellulose fibers with an advanced fibrid system in their secondary walls, made up of bundles of chain molecules (elementary fibrids and crystallites) and higher configurations (micro- and macrofibrids), the regenerated fibers rarely show such bundles. Rather, they have orderly and noncrystalline portions which, however, have flowing boundaries. In regular viscose fibers, formation of fibrids is negligible; in modifed fibers intentionally suppressed. The polynosics, on the other hand, have a distinct fibrid structure in the form of relatively stiff ropes 10 – 20 µm across. With them, the primary and secondary bundles are comparable with natural cellulose fibers.

The crystallinity, size of the morphological units, and degree of orientation in regenerated fibers are functions of the coagulation and regeneration conditions and subsequent drawing [90]. Regarding the crosswise order, it is assumed, that straight and folded chains exist side by side, with the number of straightened chains increasing with increased stretch.

Physical Properties. The structural characteristics listed in Table 20 are the outcome of process conditions and result in certain physical properties as shown in Table 21 for three types of regenerated cellulose fiber. The regular viscose fiber data in Table 20 indicate high swelling, low wet modulus, and the typical shrinking behavior of this fiber.

Table 20. Structural data of regular viscose staple, polynosic fibers, and cotton [138] (Measuring units and methods in parentheses)

	Regular viscose staple	Polynosic fibers	Cotton
Crystallinity, % (X-ray diffraction)	33 – 36	40 – 47	50 – 52
Length of crystalline portions, DP (marginal DP)	60 – 80	110 – 140	60
Thickness of crystalline portions, nm (wide-angle X-ray)	5 – 7	8 – 10	10
Accessibility of OH groups, % (H-D exchange)	60 – 70	50 – 55	50
Chain orientation, % (X-ray diffraction)	70 – 80	80 – 90	
Total chain length, DP (viscosity)	300 – 450	300 – 500	2000
Porosity, cm^3/g [139]	0.016	0.07	0.087

Table 21. Textile data of various viscose fibers

	Regular viscose staple	Modal fibers: Polynosic fibers	Modal fibers: HWM fibers
Titer, dtex	0.9 – 100	0.9 – 4.2	1.3 – 3.0
Breaking strength, conditioned, cN/dtex	1.8 – 3.3	4.0 – 6.5	4.0 – 5.5
Breaking strength, wet (5 % NaOH, 20 °C), cN/dtex	1.3	3.2	2.5
Elongation at break, conditioned, %	18 – 40	6 – 12	14 – 18
Density, g/cm^3 (65 % R.H., 20 °C)	1.50 – 1.52	1.50 – 1.52	1.50 – 1.52
Water retention, %	90 – 120	55 – 70	66 – 90
Moisture regain, % (65 % R.H., 20 °C)	13	11.5 – 12.5	11 – 12.5
Relaxation shrinkage, %	12 – 15	3 – 5	5 – 7
Wet modulus, cN/dtex	5 – 10	14 – 18	10 – 12
Mercerization	not possible	very good	under certain conditions

Table 21 indicates that the modal fibers are superior to regular viscose staple with regard to dimensional stability, i.e., the interaction of water retention, relaxation, and wet modulus. The decisive characteristic is the improved wet modulus. Figure

18 illustrates the characteristic steepness of the stress – strain curve of both wet and dry polynosics. This gives increased dimensional stability to woven fabrics even after repeated washing, as indicated in Figure 19. Their utility in certain end uses did not help the polynosics achieve economic importance as had been expected, possibly due to their fibrillating tendency.

Figure 20 shows the lengthwise sections and cross-sections of some regenerated cellulose fibers.

Figure 20. Lengthwise sections and cross-sections of some regenerated cellulose fibers [141]

The main properties of these cellulose fibers are [141]:

Viscose fibers
- Regular viscose:
  - skin – core structure
  - medium tenacity
  - medium elongation
  - 1.3 – 50 dtex (standard program)
  - bright, dull, extra dull
  - optically bleached, spun dyed
- Crimped fibers:
  - thick/thin skin – core structure
  - medium tenacity
  - medium elongation
  - good crimp (dry)
  - 2.2 – 25 dtex (standard program)
  - bright, dull, spun dyed
- High-wet-strength fibers:
  - all-skin structure
  - high tenacity
  - high elongation
  - 1.3 – 3.1 dtex (standard program)
  - bright
- Coagulated fibers:
  - all-core structure
  - low tenacity
  - higher elongation
  - irregular good crimp
  - 3.6 – 25 dtex
  - bright, dull, spun dyed

Modal fibers
- Polynosics:

high tenacity
low elongation
dimensional stability
1.3 – 3.6 dtex
bright
suitable for mercerization

HWM:

high tenacity
low elongation (but higher than polynosics)
fair dimensional stability
1.3 – 3.6 dtex
bright, optically bleached
mercerizable under special conditions

Figure 20 illustrates the data shown in Tables 20 and 21. The dark areas of the cross-sections reflect areas of higher orientation and density. Increased thickness of the skin — up to an all-skin structure — is coupled with distinct increases in fiber tenacity.

Chemical Properties. In several respects, viscose fibers behave in the same way as cotton. All these fibers are attacked by acids and oxidizing agents. If properly executed, hypochlorite and peroxide bleaching is possible. Different fibers react differently to dissolution in sodium hydroxide. Regular fibers show a dissolving maximum in ca. 10 % sodium hydroxide, even quicker as the temperature decreases, and will completely dissolve at – 5 °C. The all-core fibers are more easily dissolved in alkali than skin–core fibers.

For these reasons, polynosic and HWM fibers show different strength losses in sodium hydroxide treatments (Table 22). The hydroxyl groups can be utilized for numerous conversions.

Table 22. Strength loss (in %) of modal fibers in sodium hydroxide of various concentrations (relaxed)

	5 % NaOH	23.5 % NaOH
HWM fibers	40	60
Polynosics	15	30

Dyeing Properties. Similar to natural cellulosics, regenerated fibers can be dyed with vat dyes, Naphtol-AS, sulfuric, direct, and reactive dyes (⟶ Textile Dyeing). Particularly good fastness is obtained with reactive dyes.

Regenerated cellulose fibers absorb much more dye than natural cellulosics. The relationship between production conditions and dyeing properties of regenerated cellulose fibers is extensively described in [88]. It is said that the dye affinity of the regenerated fibers depends on the accessibility, i.e., crystallinity and degree of orientation. HWM fibers are very similar to regular viscose, while the fiber structure of the polynosics puts them nearer to cotton in this respect.

The possibility of making spun-dyed fibers offers some advantages (fastness, cross-dyeing, and low water pollution), but also some disadvantages (minimum order size, variety, and sales disposition).

Similar to dyes also other chemicals can be included in the fiber during spinning if they are resistant to the alkaline and acid processing conditions.

3.1.7. *Uses*

The varied range of natural and man-made fibers is nowadays used by the textile industry with a keener eye on the specific fiber properties. In this way, the cellulosic man-mades have acquired a leading position in certain applications and are blended or combined with other fibers to add their advantageous properties to the textiles.

Viscose fibers are used in many ways for many textile purposes: clothing, home textiles, and industrial textiles. Regular viscose staple is primarily used on its own for outerwear and nonwoven fabrics. Crimped fibers are used alone or in blends with polyester, wool, or acrylics for woven and knitted outerwear. The most successful use of HWM fibers is in blends with cotton and/or polyester in cotton-type fabrics for shirts, blouses, dresses, raincoats, bed linen, and the like. In blends with cotton, the HWM fibers act as a spin carrier and will sustain mercerization under suitable conditions. In polyester blends, they take the place of cotton; their comparatively high cross-strength makes for fabrics with good wearing properties. High-wet-strength fibers have high work-absorbing capacity (high strength at relatively high elongation) and, therefore, lend themselves as industrial textiles and nonwoven interlinings.

Viscose filament yarns are used mostly in lining fabrics as well as in ladies' outerwear and home furnishings. High-tenacity yarns continue to play an important role in industrial textiles such as automobile tires, conveyor belts, and coated fabrics.

All end uses profit by the following viscose properties: easy processing in the textile and finishing stages, hydrophilic behavior, and attractive cost/benefit ratio. Disadvantages derive from the following: relatively high density in comparison with synthetic fibers and low strength, particularly in the wet state, as well as moderate dimensional stability, which, due to the hydrophilic nature of the fiber, may be unsatisfactory for certain uses. The cost/strength ratio is also rather low. The lack in dimensional stability can often be made up by suitable after-treatment of the fabrics. Care must, however, be taken not to excessively damage the physical properties of the textile.

Viscose fibers hold a secure niche in the textile field. Since raw materials for viscose fiber production are secure, viscose can be expected to continue on an upward trend.

Outlook. Regenerated cellulose fibers hold a firm place among our textile raw materials. Solution of production problems would, therefore, be a sensible proposition. One of the aims should be an optimal cost/benefit ratio.

Regenerated cellulose fibers are popular materials for clothing, home textiles, and industrial textiles for a number of reasons. This also applies to nonwovens for household, personal care, and the wide field of medical applications, where absorption and cleanliness are primary considerations. Possible substitution by fluff has not yet been fully explored.

In the area of industrial fibers the unfavorable cost/tenacity ratio of cellulosic in comparison with synthetic fibers will result in a shift in the quantities produced in favor of synthetic fibers. This is already discernible from the figures given in Table 23. The ecological problems connected with the production of viscose fibers promote investigations in the improvement of process conditions and the search for sulfur-free processes (see Sections Cuprammonium Fibers and Tentative Cellulose Fiber Production by Other Processes – Outlook).

3.1.8. *Economic Aspects*

Growth of the world population and higher standards of living also caused an increase in the demand for textile fibers as illustrated in Table 23. It also indicates that the demand for cellulosic man-made fibers has markedly decreased and lost importance relative to the synthetics.

Table 23. World production of man-made fibers 1970 – 1996 [160]

	1970		1980		1990		1996	
	10^3 t	%	10^3 t	%	10^3 t	%	10^3 t	%
Cellulosics	3 585	43	3 581	25	3 145	16	2 900	12
Synthetics	4 809	57	10 703	75	16 006	84	21 200	88
Man-mades total	8 394	100	14 284	100	19 151	100	24 100	100

The fact that production of staple fibers kept growing slightly, while filament yarns lost more and more ground is not shown. This was a consequence of development in the nonwoven field, in garment making, and in the tire yarn industry.

Regional differences in cellulosic man-made fiber production are also interesting. Approximately 22 % is made in Western Europe, ca. 8 % in the United States, 10 % in Japan, and the remainder of more than 60 % is distributed among the other regions. Production sites are being shifted to the Far East to a certain extent (see Table 24). Of the production methods, the viscose process is by far the most important.

Table 24 gives only general trends because of differences in the computing methods and includes cigarette filter tow (acetate) as well as material for medical use (Cupro).

Table 24. Production development of cellulosic fibers in different parts of the world (in 10^3 t) [160]

	1985	1990	1995
World	3 217.6	3 146.3	3 040.4
Western Europe	709.0	700.1	684.0
Eastern Europe	994.4	833.0	272.6
USA and Canada	287.7	268.9	240.1
Japan	387.7	275.8	297.1
People's Republic of China	180.0	191.7	462.4
India	142.0	216.7	262.2
Indonesia	40.0	60.0	177.0

Depending on fiber type (titer, textile, or industrial grade), viscose filament production units should have a capacity of 10 – 30 000 t. Staple fiber units, on the other hand, should be of an even larger size, i.e., ≧ 50 000 t and more. The lower limits are governed by economic considerations and the upper limits by ecological aspects.

The future prospects of cellulose fiber production are not clear. The industry is faced with increasingly stricter environmental regulations; most production equipment is old and the market seems convinced of the advantages of synthetics. Positive

aspects of cellulosics are their hydrophilic properties, quantitative importance and the long-term availability of raw materials. These are important reasons for finding solutions to the problems so that adequate textile supplies may be secured for many years to come. Thus, in the long run, the importance of the regenerated cellulose fibers will undoubtedly increase once again.

3.2. Lyocell Fibers

In view of the problems associated with the viscose process, attempts have been made for decades to find a “shorter, simpler, sulfur-free process” for the production of cellulosic man-made fibers (see also Section Tentative Cellulose Fiber Production by Other Processes – Outlook). Of the various possible approaches, the NMMO process has now been developed to the commercial stage. The process involves dissolution of cellulose in aqueous *N*-methyl morpholine *N*-oxide (NMMO) solutions and subsequent regeneration from this solvent. This process is distinguished from other methods of producing cellulosic man-made fibers by the use of an organic solvent. This also determines the specific property profile of the fibers which justifies that they are classified as separate category within the group of cellulosic man-made fibers.

The basic principles of this process were developed around 1976 by AEC (American Enka Corp., United States) and ARLO (Akzo Research Lab. Obernburg, Federal Republic of Germany) and patented in 1980 [91]. After having discontinued the production of cellulosic staple fibers in 1983, Akzo Fibres granted licences to Lenzing in 1987 and to Courtaulds in 1990 and concentrated their development activities on filament yarns [92].

Courtaulds produced some 70 000 t/a of staple fibers under the trade name Tencel in Mobile, United States and Grimsby, United Kingdom. Lenzing has started production of staple fibers with a production volume of 12 000 t/a in Heiligenkreuz, Austria in 1997, while Akzo Nobel Fibres are preparing for commercial production of filament yarn, following successful conclusion of a market survey based on products from their Obernburg pilot plant. The technology is now also being offered to interested patries by the Thüringisches Institut für Textil- und Kunststoff-Forschung (TITK, Thuringia Institute for Textile and Plastics Research) in Rudolstadt, Federal Republic of Germany.

3.2.1. *Principles of the Lyocell Process*

The cellulose briefly described in Section Principle of the Viscose Process, NMMO, and water are mixed, after adding a stabilizer, to give a homogeneous solution [85], [92-94]. The solution is extruded into a regeneration bath consisting of an aqueous NMMO solution to obtain the desired cellulosic man-made fibers (or films). The NMMO used can be recovered at > 99 % and recycled.

A schematic of the process is depicted in Figure 21. As Figure 21 shows, the process — like the production process for synthetic fibers — is short and the regeneration bath can be recycled almost completely. As in the viscose process, certain substances can be added to the solution to impart specific properties to the fibers.

Figure 21. Lyocell process

3.2.2. *Process Description*

The cellulose is introduced into a mixture of NMMO and water. The slurry (which should be as homogeneous as possible) of, e.g., 13 % cellulose, 20 % water, 67 % NMMO, and some stabilizer is then adjusted to 14 % cellulose, 10 % water, 76 % NMMO, and stabilizer by hydroextraction, to dissolve the cellulose (see phase diagram, Fig. 22). The solution of this composition is extruded at temperatures slightly higher than 100 °C into an aqueous NMMO bath whose composition is beyond the solution range for cellulose. The fibers or films thus obtained are washed and dried. The regeneration bath is purified, concentrated and reused [92].

Figure 22. Phase diagram

3.2.3. *Fiber Properties*

Although lyocell fibers also consist of regenerated cellulose II, their properties differ substantially from those of other cellulosic man-made fibers. This difference can best be demonstrated on finished textiles. That is why Table 25 compares the requirements for four textiles typically made from viscose filament yarn with the performance of traditional viscose and lyocell yarns. Table 25 shows that the requirement profiles of the textiles are met by conventional yarns, except for three types of embroidery yarns. It is also evident from Table 25 that with lyocell fibers comparable but lighter textiles with equal good use properties can be obtained which correspond to fashion trends and customers' wishes [92].

Table 25. Comparison of requirement for four typical viscose yarns with performance properties of classical viscose and lyocell yarns, according to [92]

	Requirement for ladies' outerwear					Performance	
	General requirements	L	S	C	E	Enka Viscose (bobbin)	NewCell (current performance)

= Can be produced without problems, no discernible differences in properties for consumer; > Production advantages; + Better than reqired.

However, lyocell fibers have a special property that must be taken into account in processing and use. When subjected to a rubbing treatment, they will — especially in the wet state — form fibrils influencing the feel and appearance of the fabric. This is of advantage for producing a soft handle and/or a peach-skin fabric surface. If this is not desired, various possibilities exist to eliminate this property partially or totally (either during fiber production or aftertreatment of the textiles). These examples and the consequences for fabric design demonstrate that lyocell fibers are no substitutes for viscose fibers, but a fiber group of its own which, when put to appropriate use, opens up new possibilities for textile design without causing the kind of problems associated with viscose fibers [95], [96].

The characteristic of lyocell fibers can also be advantageously utilized in hetero-yarns, specialty textiles, and nonwoven fabrics with specific properties.

3.3. Cuprammonium Fibers

Present Situation. Production of cellulosic fibers after the copper oxide ammonia process (cuoxam process) began to decline in the early 1960s. The reasons were the outdated production equipment, the limited possibilities to increase the variety of fiber types available, and the sweeping success of the synthetics. At that time, virtually no one would have predicted the comeback of cuprammonium fibers. Moreover, elimination of the Cu ions from wastewaters seemed an unsurmountable obstacle (hazard for biological water reprocessing). In addition, the fibers were suitable for only a limited range of textiles that was waning under pressure from the synthetics. On the other hand, the largest producer of this type of fiber, Bemberg AG (now Akzo Nobel Fibres AG), diverted its research and development efforts from 1965 on to membranes and used the cuoxam solution for the manufacture of flat and tubular membranes and hollow fibers, currently the standard material worldwide for blood dialysis (Cuprophan). In artificial kidneys, they serve hundreds of thousands of kidney patients as the first artificial organ ever made [142-145]. Membrana — a business unit of Akzo Nobel Fibres — is the only producer of these hollow fibers in the Federal Republic of Germany. Cuprammonium fibers are also made in other countries: in Italy by Bemberg S.p.A., Gozzano (Novara) (filament); in Russia by Chemical Fiber Combine Kalinin (staple); and in Japan by Asahi, Nobeoka (filament and staple).

In view of the decreased importance of cuprammonium filaments and staple, we shall limit ourselves to a short description of the process principles [146-148].

Production. There are no essential differences between filament and staple production. Linters or cellulose pulp, or a

mixture of them is opened and mixed with copper hydroxide or a basic copper salt in the presence of a highly concentrated solution of ammonia in water. This results in a viscous spinning solution, which is filtered and deaerated. The method is simpler than the viscose process. The filaments are spun after Thiele's spin-drawing method by extrusion through relatively large spinning holes into a vertical water stream and high stretching. This is followed by copper extraction, neutralization, finish application, and drying. Currently, the process is continuous from start to bobbin/section beam, but some “historical” apparatus is still in use for separate spinning/winding, scouring, drying, and spooling.

Raw Materials. Starting material is generally bleached linters, but a mixture of wood pulp and linters is also occasionally used. It is customary to prepare the linters in a 1 % cuoxam solution at 20 °C to a 25 mPa · s viscosity; wood pulp is adjusted to 16 – 24 mPa · s viscosity at 20 °C, reflecting a polymerization degree (DP) of 1 000 – 1 200 and 800 – 1 000, respectively. Peculiar in cuprammonium fiber spinning from pulp is the fact that the cellulose is not treated with sodium hydroxide, with the result that none of the hemicellulose is washed out. For this reason, the pulp should have a low hemicellulose content (< 4 %).

The cellulose is dissolved in basic copper sulfate — obtained from recycling — in complex compounds with ammonia.

Spinning Solution. As a rule, the cellulose is moistened and immersed in the dissolving liquid made up of ammonium hydroxide and copper salt (basic copper sulfate or copper chloride). Since heat is released during the reaction (ca. 40 kJ/kg spinning solution), cooling is recommended so that the temperature does not exceed 25 °C. Heating causes discoloration due to the reaction of copper hydroxide with ammonia, cellulose with copper(II) aminehydroxide hydrate, and the basic copper salt with sodium hydroxide giving ammonium copper(II) hydroxide hydrate. Starting as a highly viscous mass, agitation requires very strong straight or helical mixing blades. The spinning solution is then filtered through presses equipped with noncorroding metal fabric packs (nickel or stainless steel), mesh size 40 – 70 µm. Finally, the filtered spinning solution is deaerated to remove air bubbles; at the same time some of the excess ammonia is eliminated. Depending on the spinning conditions, the solution will then contain 4 – 11 % cellulose, 4 – 6 % Cu, and 6 – 10 % NH_3, and have a viscosity of ca. 200 Pa s at 20 °C. When spun-dyed or delustered fibers are desired, inorganic and/or organic pigment dyes are added.

The solution is very stable. Stored in air-tight vessels, its composition will not change and the Υ-value remains constant, ensuring unchanged coagulating properties.

Spinning Methods [148], [149]. Cuoxam cellulose solutions are always spun according to the wet process (⟶ Fibers, 3. General Production Technology), with one or two bath passages. Strong coagulants are, for example, concentrated sodium hydroxide [150] or 3 – 30 % sulfuric acid. Single-bath wet spinning in NaOH is used for coarse filaments such as upholstery stuffing and hollow fibers [151], [152]. In this case, a bath like that in viscose fiber production is used. A commercial single-bath process using acid and salt is under consideration.

Thus far, however, the Thiele spin-drawing method in a virtually neutral bath is the rule. Vertical spin-draw funnels of glass or transparent plastic are used [153]. The spinning speed of about 150 m/min is very slow compared with the speeds in synthetic fiber spinning. Trials were made to adapt the Thiele funnel spinning method for higher speeds as well.

In several patent applications, Asahi Kasei Kogyo [154] describes methods in which the threads coming from conventional spinning funnels are led over longer drawing and coagulation distances to be finally deposited in a random layer on a perforated conveyor belt for transportation through the subsequent production stages (copper extraction, washing, finish application, and drying). This method is claimed to allow spinning speeds of up to 800 m/min.

Aftertreatment. The plastic and, therefore, mechanically sensitive yarns made up of 20 – 230 single filaments are freed from copper and aftertreated in one continuous operation.

The sheet of parallel threads spun by batteries of several hundred spinning points in staggered rows (thread spacing = 2 – 4 mm) meanders through a bath of 2 – 6 % sulfuric acid and is rinsed in two or three water baths to remove the acid. Finally, the yarn sheet is immersed for finishing and dried on heated drums or in drying chambers to a residual moisture content of ca. 11 % for winding onto beams or bobbins.

American Bemberg Corp. (Beaunit Mills Inc.) introduced a continuous spinning method, in which the funnels are arranged at an angle in a staggered row and the freshly spun yarns are led as a sheet on a straight path through shallow troughs. After the yarns have dried, they are wound onto bobbins [155]. This method is still used in Italy and Japan.

Cuprammonium Nonwovens. In [156], an apparatus for the production of nonwovens from cuprammonium filaments is described. It follows the funnel spinning and drawing principle, although with a rectangular spinneret arrangement from which the threads (ca. 90 000) cascade onto a partially permeable conveyor belt which traverses and causes crosswise entanglement of the yarns. As cuprammonium filaments will securely bake together in an ammoniacal medium, a nonwoven fabric is formed whose thickness and stability can be varied via crossing points and fusion. Production speed is claimed to be ca. 35 m/min.

Cuprammonium Staple. The spinning solution is almost the same as in filament spinning, except that a 1 – 2 % lower ammonia concentration is used to reduce the tendency of the filaments to stick together. Sticking may help in filament spinning, but is disturbing in staple production.

The dimensions of the funnels are much larger. The spinnerets are 80 – 100 mm across and have 2 000 – 3 000 holes of 0.5 – 1 mm across. The filaments emerging from 50 – 100 funnels are collected into thick tows. Aftertreatment takes place in the form of filament tow or cut to staple lengths.

For conversion into fiber laps, 5 – 10 tows are laid parallel and led through troughs of 50 –100 mm width and 10 – 20 m length and are rinsed in the same way as filament yarns. After drying, the moisture content is readjusted to 11 %. Alternating

application of strain and relaxation during wet treatment gives the filaments a regular crimp [157].

Staple fibers with a coarse irregular crimp and a rough surface are obtained if the freshly spun plastic threads are cut into 40 – 150 mm lengths on special machinery [158] and deposited on screen belts for tensionless aftertreatment [146, p. 273], [159].

Recovery of Chemicals. The copper from the ammonia baths is bound by ion exchangers. The “spinning acids” obtained during acid removal and regeneration of the “blue threads” are used to regenerate the ion exchangers. In this way, the acids concentrate around the copper. Neutralization with alkaline water gives basic copper sulfate, which is filtered off and reused to set the spinning solution.

Lately, electrolytic methods have been devised. Copper recovery is $\geqq$ 99 %. In addition, part of the ammonia — some 40 – 50 % — is recovered by distillation of the spin bath in special columns.

From the ecological point of view, the cuoxam process no longer poses any problems. At present, it is superior to the viscose process in this respect.

Properties. The most striking properties of cuprammonium fibers are fineness of the filaments, silklike appearance, and silky touch. In this respect, they are far superior to viscose yarns. Moreover, their inner structure makes hollow fibers particularly suitable for blood dialysis. In other respects, they are similar to viscose filaments without, however, reaching the high strength level of the industrial yarns in commercial production and high crimp properties.

3.4. Tentative Cellulose Fiber Production by Other Processes – Outlook

As mentioned earlier, the image of the cellulosics had come under pressure. This first resulted in resignation, as may be inferred from the fewer publications, which are a measure for research activity. After the first oil crisis in November 1973, public thinking changed. In the cellulose fiber field, various activities were initiated. Work was resumed to improve the viscose process with the intention of reducing air and water pollution; other investigators looked for ways of eliminating sulfur from the dissolving process. Assistance came from the plant breeding side in the form of higher cellulose yield per acre.

Air and water pollution was attacked from three sides: first, the reduction of chemicals to limit the problem; second, collection of chemicals where they are generated, concentration where possible, and transportation to ancillary treatment equipment; and third, improvements in the waste treatment plants. For details on waste air treatment see [82]. Suitable custom-tailored water treatment plants are available.

Besides, it must be remembered that the viscose process has set standards of cost, quality, and variety, which any new process must at least equal, if not surpass. Research which shows the possibility that cellulosics may be produced by more efficient methods gives reason for hope [82].

Successful research using NMMO as solvent for cellulose led to the start of staple fiber production (Courtaulds in the United States and the United Kingdom and Lenzing in Austria; see Section Lyocell Fibers). It is anticipated that also filament yarns will be produced by this process (Akzo Nobel Fibres). The limited variations in the process limit the variety of fiber types produced and their area of application. Experiments with cellulose carbamate [82], [84], zinc chloride – water, sodium hydroxide – water [85], and DMA/LiCl, DMF/LiCl, or DMSO/LiCl [82] as solvents have not been successful thus far. The fibers were either strong enough but too low in maximum elongation, or they were unsatisfactory as far as all physical properties were concerned. In addition, problems arose with optimizing certain production parameters (cellulose concentration, temperature, production conditions, utilization of byproducts, recycling of auxiliaries, etc.).

The insight gained from these experiments and the decades of experience with viscose processing, combined with progress in the petrochemical field, will hopefully lead to useful regenerated cellulose fibers without the help of sulfur compounds. It was intended that the new sulfur-free process should also produce a large variety of types of cellulosic fibers. According to the experience gained, this variety can probably best be obtained by modifications in the regeneration process of dissolved cellulose derivatives.

4. Ground Cellulose/Powdered Cellulose

Marc Mohring and Harald Schlosser

4.1. Production

Powdered cellulose is obtained from pulp cellulose by milling and fractionation (Figure 23). Because cellulose, hemicellulose, pectin, and lignin are all incorporated into pulp, chemical reprocessing (chemical pulping) is required for the preparation of pure cellulose. The Kraft (sulfate) or sulfite process is usually used (⟶ Paper and Pulp – Pulp). The preferred raw material for the economical production of cellulose is wood followed by annual plants such as straw.

Figure 23. Production of powdered cellulose

Powdered cellulose (Figure 24, top) is obtained from cellulose in several milling and fractionating steps. Size reduction can be performed with jet, pinned-disk, beater, cutting mill, or hammer mills, or in pan grinders. Fibrillated powdered cellulose (Figure 24, middle) is obtained by wet grinding of the cellulose. Products with a defined particle-size distribution (Figure 25) are obtained by sieving and classifying.

Figure 24. SEM images (×300) of powdered cellulose and microcrystalline cellulose

Top: powdered cellulose; Middle: powdered cellulose, highly fibrillated; Bottom: microcrystalline cellulose

Figure 25. Particle-size distribution of a powdered cellulose (Arbocel BE 600-10 TG)

To minimize dust formation, improve flowability, and reduce the volume for transport, processes for compacting, granulating, pelletizing, and extrusion of cellulose have been developed.

Microcrystalline cellulose (MCC; Figure 24, bottom) is produced from highly pure cellulose. The more easily accessible amorphous components are released by partial hydrolysis with dilute mineral acids. In this way the crystalline fraction is increased, while the degree of polymerization is reduced by acid treatment to an average DP value (degree of polymerization) of 300. In contrast, native cellulose has a DP of ca. 3000.

4.2. Properties

The physical properties of cellulose are determined by the raw material and the milling technique used. The milling process not only regulates the fiber length and fiber thickness, it also influences fiber properties such as water-binding capacity.

Selected properties of some powdered celluloses (Arbocel) and of a microcrystalline cellulose (Vivapur) are listed in Table 26.

Table 26. Selected properties of some powdered celluloses (Arbocel) and a microcrystalline cellulose (Vivapur)

Parameter	Arbocel BE 600–10 TG	Arbocel BE 00	Arbocel BC 1000	Arbocel FIF 400	Vivapur 101
Fiber length, µm	18	120	700	2000	50
Fiber diameter, µm	15	20	20	35	50
Whiteness, %	85 ± 5	86 ± 5	86 ± 5	82 ± 5	86 ± 3
Shape	fiber	fiber	fiber	fiber	particle
Bulk density, g/L	230 – 300	150 – 180	30 – 45	10 – 25	320
Ash content, %	0.3	0.3	0.3	0.3	0.05
pH value	6 ± 1	6 ± 1	6 ± 1	6.5 ± 1	6.5 ± 1
Water-binding capacity, %	400	520	1200	1350	300

Fiber lengths from 18 to 2200 µm can be produced. The individual fractions have a production-dependent particle-size distribution.

The *fiber diameter* is set by nature and differs corresponding to the type of cellulose.

Whiteness is determined with a spectrometer at 461 nm. Highly pure cellulose has a degree of whiteness of over 90 %.

The *bulk density* is dependent on the fiber length. By using a compacting process, the bulk density can be increased up to 600 g/L. Bulk density is determined according to DIN 53468.

For determination of the *ash content*, the sample is heated at 850 °C in a muffle furnace. Highly pure cellulose has an ash content of max. 0.3 %.

The *pH value* is determined according to NF XVII.

The *water-binding capacity* is determined according to the AACC method. The water-binding capacity depends on the fiber length and the degree of fibrillation. Cellulose fiber can bind up to 15 times its own weight of water.

4.3. Uses

The large range of applications for powdered cellulose can be divided into two main categories:

1) Cellulose functions as a process fiber during the production of semi-finished and end products; it helps to speed up processing and to reduce manufacturing costs.
2) The properties of intermediate or end products can be improved by the use of cellulose: increasing viscosity or improving flowability of dustlike products by converting to resoluble granules.

Cellulose has been used since the mid-1990s as a *disintegration agent* for laundry detergent tablets. Laundry detergent tablets are mainly used in Europe. They have a market share of ca. 10%. Cellulose fiber is also used as a disintegration agent for pigment granulates. Swelling pressure is built up by the capillaries of the cellulose. The fibers increase their volume several times and thus lead to a quick and complete disintegration of granulates, pellets, and tablets.

In spice mixes and grated cheese, cellulose fiber is used as a *flow agent* and *anticaking aid*. It acts as spacers between the individual particles and prevents clumping of the particles by its water-binding capacity.

Cellulose acts as a *transport medium for liquids*: it extracts water and dries but can also bring liquids into a product. Because of their coiled shape, the fibers forms drainage channels and thus speed up the transport of liquids. This transport step is not directionally fixed, but rather is determined by a concentration gradient. During drying water must be transported from the interior to the surface. Thus, for example, in the manufacture of cardboard articles, the drying time can be shortened and energy costs reduced. When manufacturing synthetic leather, cellulose is used to speed up the rinsing out of the organic solvents and thus optimize the precipitation process.

Cellulose fibers are used as a *filter aid*. They form a filter cake in suspensions with only a small amount of solids. Slimy solids form dense, compact filter cakes during separation which are difficult for the filtrate to penetrate. The fibers ensure a loose, porous filter cake with good permeability. Some examples of applications are filtration of titanium dioxide (sulfate process), beverages, dextrin (starch gum), and glucose.

In pharmaceuticals and in technical applications such as dishwasher detergent tablets, cellulose is used as a *tabletting aid*. Cellulose makes it possible to reduce the pressing power but maintain the same tablet hardness, increasing the running efficiency and output of the tabletting press.

Due to the high length-to-width ratio (up to 100:1) and the high degree of fibrillation, the fibers form a three-dimensional network. This reinforcing function of the fibers can be used to lend food products an improved texture. In the construction industry (e.g., cement tile adhesive, concrete spacers) the fibers provide improved structural stability.

1. Inorganic Cellulose Esters

Definition. Cellulose esters are cellulose derivatives which result by the esterification of the free hydroxyl groups of the cellulose with one or more acids, whereby cellulose reacts as a trivalent polymeric alcohol. Esterification can be carried out by using mineral acids as well as organic acids or their anhydrides with the aid of dehydrating substances. Cellulose nitrate [*9004-70-0*] is the most important and only industrially produced inorganic cellulose ester (abbreviation CN, according to DIN 7728, T 1, 1978). A comprehensive bibliography on inorganic cellulose esters may be found in [12–19].

Historical Aspects [20]. The nitric acid ester of cellulose is the oldest known cellulose derivative and is still the most important inorganic cellulose ester. The term "nitrocellulose" is still used, but it is not the precise scientific term for cellulose nitrate. Cellulose esters were first described and industrially used at a time when the structure of esters was unknown and information on the polymeric primary material cellulose was not yet available.

The nitration of polysaccharides with concentrated nitric acid had already been described in 1832. H. Braconnot obtained a white and easily inflammable powder when he transformed starch with nitric acid. The product obtained was xyloidine. Th.-J. Pelouze treated paper with nitric acid and obtained an insoluble product containing ca. 6 % nitrogen which he called pyroxiline and which he provided for military use.

C. F. Schönbein and R. Böttger are considered to be the inventors of so-called gun cotton (1845). They transformed cotton with a mixture of nitric and sulfuric acid into a highly nitrated product that could serve as a substitute for black powder. Production on an industrial scale was stopped in 1847 because its extremely rapid catalytic decomposition was the cause of numerous plant explosions. Production was legally prohibited in 1865.

The use of cellulose nitrate as an explosive brought new momentum to its further industrial and scientific development, as well as to its economic significance. F. Abel made a basic breakthrough in 1865 when he succeeded in developing a safe method of handling. He was able to achieve a better washing of the adhering nitrating acid and a hydrolytic decomposition of the unstable sulfuric acid ester by grinding the nitrated fibers in water. This process allowed this product to attain military importance for its use as gunpowder.

In 1875, A. Nobel phlegmatized nitroglycerine by mixing with cellulose nitrate and discovered blasting gelatin. In the 1880s, smokeless gunpowders were developed. Vieille developed Poudre B (blanche) and Nobel developed Ballistit, the first dibasic gunpowder from cellulose nitrate and nitrogycerol. Abel and Dewar developed a similar gunpowder called Cordit.

The discovery that fibrous products could be modified by, for example, dissolution in an alcohol/ether mixture (film for wound protection) or by gelatinization with softeners brought additional uses. Films made from camphor and castor oil were used in collodium photography as carriers for light-sensitive materials (Archer, 1851). Nitrofilms found increasing use in photography and cinematography until they were replaced by nonflammable cellulose acetate films.

The year 1869 is considered to be the beginning of the age of plastics. J. W. Hyatt discovered celluloid, the first thermoplastic synthetic material. It was originally used as a substitute for ivory in the production of billiard balls.

The practical use of cellulose nitrate as a raw material for lacquers began in 1882, when Stevens suggested amyl acetate as a highly volatile solvent (Zaponlack). The nitro lacquers achieved importance at first after World War I (Flaherty, 1921), when new applications were being sought as a result of the sharply declining demand for gunpowder. Only after the possibility of depolymerization of cellulose nitrate by pressure boiling during production had become known during the 1930s it was possible to use cellulose nitrate in protective and pigmented lacquers. Thus, it became possible to use nitro lacquers for painting automobiles on the assembly line.

Cellulose xanthate [*9032-37-5*] is a cellulose ester obtained with the inorganic acid dithiocarbonic acid. Ch. F. Cross discovered this important alkali-soluble cellulose ester in 1891 while he was reacting cellulose with alkali and carbon disulfide. It represents the base of the viscose process introduced in 1894 by Bevan and Bea-

DLE for producing man-made cellulosic fibers (rayon, rayon staple) and cellophane.

Other cellulose esters with inorganic acids are presently only of theoretical interest and have not attained any industrial or economic importance.

Present Significance. Cellulose nitrate is still important, 150 years after its discovery. It is industrially produced in large quantities for diversified applications. The reasons for this are the relatively simple production process with high yields, its solubility in organic solvent systems and its excellent film-forming properties from such solutions (collodion cotton as a raw material for lacquers), compatibility and gelatinability with softeners and other polymers (thermoplastics), as well as inflammability (gun cotton for explosives). Cellulose nitrate has maintained its importance as a raw material for the manufacture of protective and coating lacquers as well as blasting agents and explosives.

Densified products, colored or pigmented chips kneaded with softeners, as well as aqueous dispersion systems with a low solvent content, are available today. They facilitate transport and processing, secure existing application forms, open up new ones, and are becoming increasingly nonpolluting.

The viscose process (see →Cellulose, Chap. 3.1.1.) with its essential intermediate cellulose xanthate will remain, because of the availability of a constantly regrowing raw material supply, an important source of textile fibers for years to come. Alternative processes are intensively being sought to reduce pollution by sulfurous decomposition gases resulting during manufacturing. Cellulose nitrite, the cellulose ester of nitrous acid, is the most prominent example.

Cellulose esters with other inorganic acids have been frequently described and investigated. Cellulose sulfate [*9032-43-3*] was of some interest because of its solubility in water, but never achieved any practical importance. Cellulose phosphate [*9015-14-9*], borate, and titanate show interesting properties such as fire retardation, but are not yet of any industrial significance.

1.1. Esterification

Mechanism. The alcoholic hydroxyl groups of cellulose are polar and can be substituted by nucleophilic groups in strongly acid solutions. The mechanism of esterification assumes the formation of a cellulose oxonium ion followed by the nucleophilic substitution of an acid residue and the splitting off of water. Esterification is in equilibrium with the reverse reaction; saponification can be inhibited largely by binding the resulting water.

Course of Reaction. The three functional hydroxyl groups on each anhydroglucose unit of cellulose are blocked by intermolecular and intramolecular hydrogen bonds and, therefore, are not freely accessible for the reaction partners. The supermolecular arrangement and microstructure within the cellulose fiber, whose intensity depends on the origin and previous history of the cellulose material, is determined by these hydrogen bonds. The accessibility to the reaction partners and the reactivity of the alcohol groups also depend on this structure.

Due to the fact that cellulose is insoluble in all common solvents, reactions to form derivatives are usually carried out in heterogeneous systems. As the reaction proceeds, new reactive centers are created so that ultimately almost all parts of the cellulose fibers are included and in special cases yield soluble derivatives which react to completion in a homogeneous phase.

Little information is available on the esterification process. The following two reaction types are under discussion:

– An intermicellar reaction, which initially consists of the penetration of the reaction partner into the so-called amorphous regions between the highly organized cellulose micelles and proceeds during the course of esterification from the surface to the innermost regions of the micelles. The reaction speed is determined by diffusion.

– An intramicellar or permutoid reaction, in which the reagent penetrates all regions including the micelles so that practically all cellulose molecules react almost simultaneously. The reaction speed is specified by adjustment of the esterification equilibrium.

Arguments for both mechanisms are based on X-ray analyses. The possibility exists that both reaction types occur and ultimately merge. This depends on the reaction conditions, especially the esterification mixture and the temperature.

The hydrogen bonds between the cellulose molecules are almost completely broken down during esterification. The introduction of ester groups separates the cellulose chains so completely that the fiber structure is either altered or completely destroyed. Whether the cellulose ester is soluble in a solvent or in water depends on the types of substituents added.

Substitution. The esterification reactions do not necessarily proceed stoichiometrically because of equilibrium adjustment. The maximal attainable substitution with a mean degree of substitution (DS) of 3 is generally not reached. A triester can only be obtained under carefully controlled conditions. The primary hydroxyl group on the C-6 atom reacts most readily, while the neighboring hydroxyl groups on the C-2 and C-3 atoms of the anhydroglucose ring react considerably slower due to steric hindrance.

Basically, esterification is possible with all inorganic acids. Limiting factors are the type and the size of the acid residue as well as the varying degree of acid-catalyzed hydrolysis, which can lead to a complete cleavage of the cellulose molecule as the result of statistical chain splitting.

1.2. Cellulose Nitrate

Summary monographs on cellulose nitrate in addition to those in the Reference list can be found in [21] and [22].

1.2.1. Physical Properties

Cellulose nitrate (CN) is a white, odorless, and tasteless substance. Its characteristics are dependent on the degree of substitution.

Density. The density of cellulose nitrate is dependent on its nitrogen content and, therefore, on the degree of substitution (Table 1).

Table 1. The density of cellulose nitrate in relation to its nitrogen content (degree of substitution)

Nitrogen content, %	Degree of substitution (DS)	Density at 20 °C, g/cm^3
11.5	2.1	1.54
12.6	2.45	1.65
13.3	2.7	1.71

The bulk density of commercially available CN types is between 0.25 and 0.60 kg/L for moistened CN cotton, 0.15 – 0.40 kg/L when converted to dry mass.

Cellulose nitrate chips, which contain at least 18 % dibutyl phthalate in addition to cellulose nitrate, have a density of 1.45 g/cm^3 (measured at 20 °C in an air-comparison pycnometer). The bulk density is 0.3 – 0.65 kg/L.

Specific Surface. The laboratory apparatus described by S. Rossin [23] is best suited for the determination of the specific surface of cellulose nitrate, which is 1 850 – 4 700 cm^2/g, depending on the fineness of the cellulose nitrate.

The determination of the inner surface according to the BET method showed dependence on the molar mass (i.e., an inner surface area of 1.44 m^2/g would correspond to a molar mass of 180 000 g and a surface area of 2.41 m^2/g would correspond to a molar mass of 400 000 g).

It must, however, be noted that the degassing temperature was lowered from the usual 200 °C to 60 °C due to the fact that cellulose nitrate deflagrates at 180 °C. It is possible that complete desorption did not take place under these conditions.

Thermodynamic Properties , see [24, pp. 137 –154]. The most important thermodynamic properties are listed in Table 2.

Table 2. Thermodynamic properties of some cellulose nitrates

Heat of formation	trinitrate	– 2.19 kJ/g
	dinitrate	– 2.99 kJ/g
	cellulose	– 5.95 kJ/g
Heat of combustion	trinitrate	– 9.13 kJ/g
	dinitrate	– 10.91 kJ/g
	cellulose	– 17.43 kJ/g

Table 2. continued

Specific heat	celluloid film (70 % CN and 30 % camphor)	1.26 – 1.76 J g^{-1} K^{-1}
Thermal conductivity	celluloid film (70 % CN and 30 % camphor)	0.84 kJ m^{-1} h^{-1} K^{-1}
Heat of solution in acetone	CN with 11.5 % N content	– 73.25 J/g
	CN with 14.0 % N content	– 81.64 J/g

Electrical Properties [24, p. 136]. The following electrical properties were measured on cellulose nitrate containing 30 wt % camphor (celluloid):

Dielectric constant
at 50 – 60 Hz7.0 – 7.5
10^6 Hz6.0 – 6.5
Dissipation factor (tan δ)
at 50 – 60 Hz0.09 – 0.12
10^6 Hz0.06 – 0.09
Specific resistance $10^{11} - 10^{12}$ $\Omega \cdot$ cm

Mechanical Properties [25]. The stress – strain diagram of cellulose nitrate films shows the elongation and tensile strength to be dependent on the size of the molecule (expressed as a term of viscosity).

The higher the molecular mass of a CN, the more elastic is the film made from it. Films become more brittle and their tensile strength declines with decreasing molecular mass (see Table 3).

Table 3. Mechanical properties of CN lacquer films

Type∗	Elongation, %	Tensile strength, N/mm^2
E 4	24 – 30	98 – 103
E 6	23 – 28	98 – 103
E 9	23 – 28	88 – 98
E 13	20 – 25	88 – 98
E 15	18 – 23	78 – 98
E 21	12 – 18	78 – 88
E 22	10 – 15	74 – 84
E 24	8 – 12	69 – 78
E 27	5 – 10	59 – 69
E 32	<5	39 – 49
E 34	<3	29 – 49

∗ According to DIN 53179: The E-type designation specifies the CN concentration (% in dry condition) in acetone which gives a viscosity of 400 ± 25 mPa · s.

Optical Properties. Cellulose nitrate films are optically anisotropic because of their microcrystalline structure. The colors change in polarized light in relation to the nitrogen content of the CN:

11.4 % N weakly red
11.5 – 11.8 % N yellow
12.0 – 12.6 % N blue to green

The index of refraction is 1.51, and the maximal light transmission is achieved at 313 nm.

Light Stability. Exposure to sunlight, and especially to ultraviolet light, has a detrimental effect on cellulose nitrate film by causing it to become yellowish and brittle. Solvents, softeners, and resins can either promote or hinder yellowing.

1.2.2. Chemical Properties

The three hydroxyl groups of cellulose can be completely or partially esterified by nitrating acid. The varying degrees of nitration can be related to the following theoretical nitrogen contents:

Cellulose mononitrate, $C_6H_7O_2(OH)_2(ONO_2)$:
6.75 % N
Cellulose dinitrate, $C_6H_7O_2(OH)(ONO_2)_2$:
11.11 % N
Cellulose trinitrate, $C_6H_7O_2(ONO_2)_3$:
14.14 % N

Cellulose nitrate with a nitrogen content between 10.8 and 12.6 % is a suitable raw material for lacquers, and CN with > 12.3 % N is suitable for explosives exclusively.

Degree of Substitution – Nitrogen Content – Solubility. The degree of substitution can be calculated from the nitrogen content of the various CN types (Fig. 1). The degree of substitution determines the solubility of cellulose nitrate in organic solvents. CN for lacquers can be classified according to its solubility in organic solvents as follows:

alcohol-soluble CN (A types)
nitrogen content: approx. 10.9 – 11.3 %
readily soluble in alcohols, esters, and ketones
moderately soluble CN (AM types)
nitrogen content: approx. 11.4 – 11.7 %
soluble in esters, ketones, and glycol ethers with excellent blendability or compatibility with alcohol
CN soluble in esters (E types)

nitrogen content: 11.8 – 12.2 % for lacquer cotton, up to 13.7 % for guncotton
readily soluble in esters, ketones, and glycol ethers

Figure 1. Variation of the degree of substitution with the nitrogen content of cellulose nitrate

Intrinsic Viscosity – Degree of Polymerization [24, pp. 85 – 121]. The mean number of anhydroglucose units in cellulose nitrate molecules is designated as the mean degree of polymerization (DP). The viscosity of the solution (at the same concentration in the same solvent) is generally considered to be a relative measure of the molecular mass. The molecular mass can be mathematically expressed as a function of the intrinsic viscosity (Staudinger – Mark – Houwink equation). For further information → Plastics, Analysis.

Distribution of the Molecular Mass. The starting material of cellulose nitrate is natural cellulose, the quality of which is subjected to annual growth cycles. It is, therefore, of great importance to have polymolecular data, such as the mean degree of polymerization and the distribution of the molecular mass, available in addition to viscosity, solubility behavior, and nitrogen values. These values are important, for example, in assessing the mechanical properties and aging processes of polymer products.

The isolation of the polymers according to their molecular mass can be achieved elegantly by gel permeation chromatography (GPC).

Chemical Compatibility. An everyday use of cellulose nitrate is in nitro lacquers, where it is dissolved in organic solvents. In this solution, cellulose nitrate is extremely compatible with essential substances in the lacquer formulation such as alkyd resins, maleic resins, ketone resins, urea resins, and polyacrylates. A large number of softeners, such as adipates, phthalates, phosphates, and raw and saturated vegetable oils are compatible with cellulose nitrate.

Chemical and Thermal Stability. Cellulose nitrate, as a solid or in solution, should not be brought into contact with strong acids (degradation), bases (denitration), or organic amines (decomposition) since they all induce a destruction of cellulose nitrate. This may proceed very rapidly and lead to deflagration of the cellulose nitrate.

The ester bonds of cellulose nitrate, which can be broken by saponifying agents or by catalysis, are responsible for its physicochemical instability. This substance-specific property is dependent on the temperature, the specimen, and whether catalytically active decomposition products remain or are removed from the sample.

Another basic instability of cellulose nitrate is observed during the production process. Mixed sulfuric acid esters transmit a chemical instability to the nitrocellulose molecule. These mixed esters are destroyed in weakly acid water during the stabilization phase of production. The long reaction time required by this procedure can be considerably shortened by increasing the reaction temperature. The time required can be reduced to only a few hours by raising the temperature to 60 – 110 °C. Under these conditions the nitrate ester remains stable; the glucosidic bond of cellulose nitrate, on the other hand, is attacked. This property is used to advantage to specifically reduce the degree of polymerization of the cellulose nitrate.

Thermogravimetry, IR spectroscopy, and electron spectroscopy (ESCA) [26], [27] have been used to determine the extent of thermally induced and light-induced decomposition of cellulose nitrate. The reaction proceeds as follows:

$$\text{Cell}-\text{O}-\text{NO}_2 \longrightarrow \text{Cell}-\text{O}\cdot + \cdot\text{NO}_2$$

It is proceeded by a series of extremely exothermic oxidation reactions triggered by the NO_2 radical, which often leads to spontaneous deflagration. NO_2 is reduced to NO and in the presence of air NO_2 is reformed, thus initiating an autocatalytic chain reaction, at the end of which the gaseous reaction products CO_x, NO_x, N_2, H_2O, and HCHO are found.

By adding stabilizers such as weak organic bases (diphenylamine) or acids (phosphoric acid, citric acid, or tartaric acid), intermediary nitric oxides can be bound and the autocatalytic decomposition prevented.

Thermal decomposition does not occur at temperatures below 100 °C. The temperature (according to [28]) at which cellulose nitrate spontaneously deflagrates is used as a measure of its thermal stability. A well-stabilized lacquer cotton has a deflagration temperature of ≥ 180 °C. The deflagration temperature of plasticized cellulose nitrate chips with at least 18 wt % softener (i.e., dibutyl or dioctyl phthalate) is ≥ 170 °C.

The Bergmann – Junk test [29] and the warm storage test are additional methods for determining the stability of cellulose nitrate.

1.2.3. Raw Materials

Cellulose. Until the beginning of World War I, the only raw material available for nitration was cellulose obtained from cotton in the form of bleached linters (as flakes or crape). This was due to the high degree of purity (α-cellulose > 98 %), which allowed a high yield and products with good clarity and little yellowing.

Especially in times when linters were scarce, it was possible to produce gunpowder from wood celluloses, even unbleached, other cellulose fibers (annual plants), and even from wood if attention was given to the adequate disintegration of the raw materials. Lacquer types obtained from wood celluloses, especially from hardwood, gave dull and mat films and lacquers with inferior mechanical properties. This is due to the high content of pentosans, which is also nitrated but is easily split by hydrolysis in conventional nitrating acid systems and thus becomes insoluble.

The development of highly purified chemical-grade wood pulp by refinement with hot and cold alkali having R_{18} values of 92 – 95 % (see Table 16) allows this type of raw material to be used in the same manner as were linters, which currently are used only for the production of special and highly viscous CN types. The highly refined prehydrolyzed sulfate pulps with R_{18} values of above 96 % are especially well-suited for nitration. The viscosity range of CN products can be adjusted in advance by choosing an initial cellulose with an adequate DP. A low ash content, and above all a low calcium content, of the cellulose is important in preventing calcium sulfate precipitation during industrial nitration.

A comparative study on the nitrating behavior of linters and wood pulps [30] shows the morphological factors of the fibers (fiber length and distribution, cross-section form and thickness of the secondary wall, and fine structure including packing density, degree of crystallization, and lateral arrangement of the fibrils), the chemical composition of the cellulose (DP and polydispersibility) as well as the type, quantity, and topographic distribution of the accompanying hemicelluloses and lignin to be responsible for the nitrating capability of celluloses. These factors determine the swelling properties and thereby the uniformity of nitration, as well as the compressibility and the relaxation capacity of the fibers, which in turn influence the retention capacity of the fiber mass. Linters with a lower acid retention capacity of 110 – 130 % are definitely superior to wood pulp (acid retention capacity of prehydrolyzed sulfate pulps up to 230 %, of sulfite pulps up to 300 %) in this respect. The suitability of a raw material for nitration can be tested by a specially developed machine that measures the compression and relaxation characteristics of a cellulose fiber pile.

Approximately 150 000 t (3.4 %) of the annual worldwide production of 4.4×10^6 t of chemical-grade pulps are used for the production of cellulose nitrate.

Industrial Nitrating Agents. The so-called nitrating acid as developed by SCHÖNBEIN, the nitric acid/sulfuric acid/water system, is still the nitrating agent of choice for industrial purposes. The highest attainable degree of substitution using this system is at DS $2.7 \triangleq 13.4$ % N. This is achieved only when the nitric acid used is not hydrated and the molar ratio of nitric acid to sulfuric acid monohydrate is 1 : 2. The optimal nitrating mixture is as follows:

	HNO_3	H_2SO_4	H_2O
molar ratio	1	2	2
wt %	21.36	66.44	12.20

Water plays a special role as far as the attainable degree of nitration is concerned. Below 12 % water there is no increase in substitution, but a higher water content results in a drastic decline in the degree of nitration (Fig. 2).

Figure 2. Dependence of the degree of esterification (DS) on the water content of the optimal nitrating mixture ($HNO_3 : H_2SO_4 = 1 : 2$)

It is assumed that increasingly hydrated nitric acid causes increased swelling and gelatinization of the cellulose so that the nitrating acid is no longer able to penetrate into the inner structures of the micelles.

The desired degrees of esterification can be adjusted by varying the nitrating acid mixture according to the CN types (Table 4), whereby in industrial processes the nitric acid content is kept nearly constant at 25 – 26 %.

The ternary system $HNO_3/H_2SO_4/H_2O$ has been extensively investigated. The results are summarized in Figure 3.

The curves of the same degrees of substitution (% N) in relation to the nitrating acid composition are presented here. The cross-hatched band identifies those areas in which the cellulose material is extremely swollen and gelatinized. Three zones can therefore be differentiated in the phase diagram:

1) Area of technical nitration:
   nitric acid 15 – 100 %
   sulfuric acid 0 – 80 %
   water 0 – 20 %
   In this range, nitric acid is present in a nonhydrated form and induces true nitration (N content 10 %). The industrially used range with 20 – 30 % HNO_3, 55 – 65 % H_2SO_4, and 8 – 20 % water is also included in this area.
2) Area of solution:
   nitric acid 0 – 10 %
   sulfuric acid 60 – 100 %
   water 0 – 40 %
   Little or no nitration takes place in this range. Cellulose is degraded to the point of complete dissolution in concentrated sulfuric acid.
3) Area of swelling:
   Nitric acid is increasingly hydrated in this range of increasing water content. Nitration decreases rapidly.

A process developed in the United States, but less important, uses magnesium nitrate instead of sulfuric acid as a dehydrating agent [31]. Magnesium nitrate can bind water as its hexahydrate. The nitrating mixture consists of 45 – 94 % nitric acid, 3.3 – 34 % magnesium nitrate, and 2.7 – 21 % water; the ratio of magnesium nitrate : water is 1.2 – 2.2 : 1. A cellulose nitrate with an N content of 11.9 % was obtained, for example, with 64.5 % HNO_3, 19.5 % $Mg(NO_3)_2$, and 16 % H_2O. This nitrating system is appropriate for a continuous process, in which waste and washing acid are reprocessed in ion exchangers and the magnesium nitrate is recycled. Thus, acid and sulfate no longer pose a waste disposal problem.

1.2.4. Production

The flow diagram (Fig. 4) shows the industrial production of CN according to the mixed acid process. The viscosity of the end product is determined by the choice of the initial cellulose, and the degree of nitration is determined by the composition of the mixing acid. The final viscosity adjustment follows during the pressure boiling step (see Section 1.2.4.3).

1.2.4.1. Cellulose Preparation

Cotton linters with a moisture content of up to 7 % are mechanically disintegrated homogeneously. Pressed pulp sheets must be appropriately shredded to obtain rapid and uniform nitration. Spruce or beech celluloses, preactivated with 20 % sodium hydroxide (mercerization),

Figure 3. Composition of the nitrating mixtures and attainable N contents of cellulose nitrates

Figure 4. Flow diagram of cellulose nitrate production

Table 4. Industrially used nitrating acid solutions

CN type	Nitrating acid			N content,	DS
	% HNO_3	% H_2SO_4	% H_2O	%	
Lacquer cotton A	25	55.7	19.3	10.75	1.90
Celluloid cotton	25	55.8	19.2	10.90	1.95
Lacquer cotton AM	25	56.6	18.4	11.30	2.05
Dynamite cotton	25	59.0	16.0	12.10	2.30
Lacquer cotton E	25	59.5	15.5	12.30	2.35
Powder cotton	25	59.8	15.2	12.60	2.45
Gun cotton	25	66.5	8.5	13.40	2.70

were formerly used for this purpose in the form of crape papers with a mass per unit area of ca. 25 g/m^3. To avoid the costly transformation of the cellulose to paper sheets, a process was attempted to obtain a loose product resembling linters by direct disintegration of pulps to fibers. A moisture content of 50 % proved to be optimal for nitration and washing out the acid. The required drying of the cellulose flakes before nitration proved to be disadvantageous.

The Stern shredder [32], in which the pulp sheets are torn rather than being cut into small elongated shreds to avoid compression at the edges, was a definite improvement. Currently, cellulose for nitration is used in the form of fluff, shreds, or chips. The packing density and compression behavior of the cellulose fibers in the fiber pile are decisive factors for the swelling and nitration kinetics, as well as the acid retention capability [30].

1.2.4.2. Nitration

Nitration on an industrial scale is still frequently carried out according to a batch process that was developed from a process described by DuPont in 1922. The equipment is constructed of stainless steel. The adjusted and preheated nitrating acid reaches the stirring reactor that is charged with cellulose by means of a measuring system; a large excess of acid (1 : 20 to 1 : 50) is added to retain the ability of the reaction mixture to be stirred and to ensure that heat is carried off. The nitrating temperature is between 10 °C (dynamite type) and 36 °C (celluloid type). The total heat of reaction is estimated to be over 200 kJ per kg of CN, of which the enthalpy of formation of CN is about one-third.

Even though the reaction is nearly complete after ca. 5 min, the mixture remains in the reactor for about 30 min. The temperature must remain constant (cooling), since hydrolytic degradation processes that lead to considerable losses in yield begin at temperatures as low as 40 °C.

The theoretical yield of commonly used industrial types with a DS of 1.8 – 2.7 ($\hat{=}$ 10.4 – 13.4 % N) is between 150 and 176 % with respect to cellulose. The practical yield, however, is up to 15 % lower and depends on the type and purity of the cellulose, as well as on the temperature and duration of nitration. Losses arise from the inevitable complete decomposition of cellulose to oxalic acid by way of oligo- and monosaccharides, whereby the nitric acid is reduced to nitrogen oxides, NO_x. In addition, mechanical losses during the subsequent separation process, due particularly to short fibers (cellulose from hard wood), must also be taken into consideration.

The reaction mixture is drained from the reactor into the centrifuge, where the excess acid is separated and removed at high speed and reprocessed for recycling. The mixture must remain moist so that it does not ignite and deflagrate.

The degree with which the product retains acid after separation is of economic importance because of the acid loss and the expense of the ensuing washings. Linters with an acid retention of 100 – 130 % clearly surpass wood celluloses in this respect which, depending on the wood and cellulose type as well as its processing, can retain up to 3 times more adhering acid relative to CN [30].

The still acid-moist product is immediately placed into a great excess of water (consistency 1 %) so that the adhering acid is displaced as rapidly as possible and the saponification of the CN is prevented.

Continuous nitrating processes, which are more economical, were developed in the 1960s

[33], [34]; they ensure a more uniform product quality and are safer to handle. The nitrating system consists of two or more consecutively arranged straight-run vats or tube systems containing conveyers (screw conveyer or turbulence stirring apparatus) which forward the reaction mixture. The prepared cellulose is directed into this cascading equipment from storage bunkers over automatic weighing scales and continuously mixed with the added nitrating acid. It is important that the cellulose is rapidly added and immediately covered with acid. There it remains for 30 – 55 min. A newer process using a continuous loop-formed pressure reactor [35] requires the cellulose to remain only for 6 – 12 min. The reactant is then sent into a continuously operating special centrifuge, where the excess acid is separated and simultaneously taken up with water. The fact that the reactant remains only a few seconds reduces the risk of spontaneous deflagration and saponification.

Figure 5 shows schematically the continuous process according to Hercules [31].

The broken-up and preconditioned cellulose (a) is brought by way of the automatic scales (b) to the continuous reactor (c). The reaction product is centrifuged in a washing zone (d) and simultaneously washed by zones with water in a countercurrent. The product leaves the centrifuge almost free of acid, and the washed out acid can be recycled and reused almost without loss [36].

1.2.4.3. Stabilization and Viscosity Adjustment

The prestabilization step following the prewashing further purifies the product by means of repeated washing and boiling with water that contains 0.5 – 1 % acid residue. The batch method requires large amounts of space, water, and energy; the required boiling time varies between 6 (celluloid type) and 40 h (guncotton). Automatic continuous processes have been developed in this case as well [37].

Most of the remaining sulfuric acid is removed during prestabilization, since it would promote the catalytic self-decomposition of CN. The sulfuric acid is bound by adsorption and esterified. A total sulfate content of 1 – 3 % was found in weakly nitrated CN, of which 70 – 85 % is in the form of the acidic sulfuric acid semiester, while highly nitrated CN contains only 0.2 –0.5 % total sulfate, of which 15 – 40 % is thought to exist as an ester. Semiesters can be easily saponified and washed out by boiling with water. It is not yet certain whether the so-called resistant sulfate content exists in the form of the neutral sulfuric acid ester or the physically adsorbed sulfuric acid.

The desired final viscosity of the CN is adjusted in the following process step, which is pressure boiling (digestion under pressure) in a consistency of 6 – 8 % at 130 – 150 °C, by means of specific degradation of the degree of polymerization. The remaining extremely low sulfuric acid content induces hydrolytic decomposition at this temperature and under pressure. The viscosity can, for example, be reduced to 1/10 of the initial viscosity within 3 h at 132 °C by using this process. This process made the development of high solid coating and protective nitro lacquers possible. The stabilization process of guncottons is accelerated by pressure boiling; dynamite wools are usually not pressure boiled.

Further product losses are due to chain degradation ranging from soluble cleavage products to oxalic acid. Nitrous gases (NO_x) are released by the reduction of nitric acid, which must be continuously drawn off to avoid decomposition of CN.

Pressure boiling can be achieved batchwise in autoclaves, as well as continuously in a tube reactor of 1 500 m in length and 100 mm in diameter, e.g., with direct steam. A one-pot process in which prestabilization, pressure boiling, and poststabilization are carried out in one operation is described in [38].

During the stabilization process, the remaining sulfuric acid is almost completely removed by additional washing and boiling. While celluloid and lacquer types are finished in flaky, fibrous form, guncotton must be ground. This is done in grinding hollander engines at 12 – 15 % consistency or continuously in a series of cone refiners, whereby the material is gradually concentrated from 3 to 10 % between the various grinding steps. Sorting steps are inserted by hydrocyclones during the final washing processes. The last acid remnants in the fiber capillaries are removed during the grinding process by means of diffusion against water. Weak bases, sodium carbonate, or chalk are used to main-

Figure 5. Continuous cellulose nitrate production according to Hercules
a) Preconditioning; b) Auto-matic scale; c) Reactor; d) Washing zone; e) Centrifuge

tain a pH of 7. Stabilizers (organic acids) may be added during this step.

1.2.4.4. Displacement and Gelatinization

A water-wet CN cotton with a water content of 25 – 35 % remains in the centrifuge after the final separation and is then packed into drums or PE sacks.

Water contained in celluloid and lacquer types is displaced by alcohols specified by the processors (ethanol, 2-propanol, *n*-butanol) in displacement presses or displacement centrifuges. Continuous processes prevail here also [39]. The resulting aqueous alcohols must be distilled to remove the water.

The water-wet CN cotton can be gelatinized with softeners such as phthalates in kneading aggregates and dried on drum or band driers for the production of CN chips [40], [41]. Colored chips are obtained by adding carbon black or pigments from which colored enamels can be produced without the use of ball mills or roller mills.

1.2.4.5. Acid Disposal and Environmental Problems

The nitrous gases formed during the nitrating and stabilizing side reactions are drawn off and washed out in trickling towers. The lower nitrogen oxides are regained after oxidation as 50 – 60 % nitric acid.

The waste acids resulting from the first separation contain 2 – 3 % more water and 3 – 4 % less nitric acid than the initial mixture. They are circulated in a closed system and constantly regenerated with nitric acid and oleum. The acid that adheres to the product must also be replaced.

The proportion of adhering acid depends on the initial cellulose and the CN type. It ranges between 80 % (guncotton) and up to 200 – 300 % (lacquer types) with regard to CN and is removed with the water used for washing and boiling.

Aside from the economic aspects of acid loss in wastewater, environmental considerations are beginning to play an increasingly important role. While older manufacturing facilities using simple centrifuging to remove waste acid produced 300 m^3 of water per ton of CN, containing 0.5 %

acid and with a pH of 1, it was possible to reduce the volume of wastewaters to a fraction of its previous volume by almost completely closing the cycles.

Before proceeding into the draining ditch, the wastewater must be separated from the hardly decomposable sludge consisting of cellulose and CN, and then be neutralized. The sulfate proportion can be reduced by calcium sulfate precipitation, while the nitrate proportion remains completely in the wastewater. Organic matter of communal sewage, for example, can be biologically decomposed without additional oxygen, whereby nitrates disappear almost completely as a result of biological denitrification.

The salt/acid process with magnesium nitrate (see Section 1.2.4.2) is more favorable with regard to the wastewater problem. Sulfates are completely absent, and magnesium nitrate is recycled and, therefore, causes no water pollution problems. The amount of wastewater can be reduced by 80 % and the nitric acid requirement by 83 % in comparison to the formerly used discontinuous processes.

1.2.4.6. Other Nitrating Systems

Numerous attempts have been made to improve nitration by the introduction of other nitrating systems, or at least to increase the degree of substitution. Further details may be obtained from [12], [14], [17], and [21]. Table 5 gives a summary of alternative nitrating systems, none of which was able to displace the ternary system $HNO_3/H_2SO_4/H_2O$ for industrial nitration.

Nitration with pure nitric acid is possible in principle. Esterification is not possible with acid concentrations below 75 %. Acid concentrations less than 75 % cause the formation of the unstable so-called Knecht compound, which has been described as either a molecular complex or an oxonium salt of the nitric acid. Cellulose nitrates with 5 – 8 % N, which dissolve in excess acid, are formed at acid concentrations of 78 – 85 %. Nitrogen contents of 8 – 10 % are attained at concentrations between 85 and 90 % HNO_3; these products have a strong tendency to gelatinize. Heterogeneous nitration without apparent swelling takes place at a HNO_3 concentration above 89 %, and 13.3 % N can be achieved with 100 % HNO_3. Nitration can be increased to 13.9 % N with 100 % HNO_3 by addition of inorganic salts such as sulfates, acid phosphates, and particularly nitrates, preferably in a 15 % concentration.

Table 5. Nitrating systems

Nitrating system	Max. N content, %	Comments
$HNO_3/H_2SO_4/H_2O$	13.4	Industrial nitration
$HNO_3 < 75$ %		"Knecht compound," unstable
78 – 85 %	8	Dissolution in the nitrating acid
85 – 89 %	10	Gelatinization
90 – 100 %	13.3	No swelling
HNO_3 + nitrates, sulfates, phosphates	13.9	
HNO_3 vapor	13.75	Slow reaction, stable nitrate
HNO_3 vapor + nitrogen oxides	13.8	
N_2O_5	14.12	
N_2O_5 in CCl_4	14.14	Trinitrate
HNO_3 in CH_2Cl_2	14.0	
HNO_3 in nitromethane	14.0	Homogeneous reaction
$HNO_3 + H_3PO_4/P_2O_5$	14.04	Rapid reaction without decomposition (polymer analogue)
	14.12	After extraction with methanol
HNO_3 + acetic acid/acetic anhydride	14.08	Great stability
	14.14	After extraction with ethanol
HNO_3 + propionic acid/butyric acid	14.0	

The nitric acid/phosphoric acid system is of special interest in a 1 : 1 ratio with 2.5 % phosphorus pentoxide added, with which an almost completely nitrated product of great stability was achieved. The nitric acid/acetic acid/acetic anhydride system in a ratio of 2 : 1 : 1 gives highly nitrated and highly stable products in which the fiber structure remains intact largely. After extraction of these nitrates with water or alcohol, the theoretical degree of substitution of the trinitrate may be attained.

Nitrating systems which achieve a high degree of nitration without degradation of the cellulose chain are of special scientific interest. This process is known as polymer analogous nitration. After a critical examination of all known nitrating mixtures, the nitric acid/acetic acid/acetic

anhydride system in a ratio of 43 : 32 : 25 at 0 °C [42] was recommended for determining the molecular mass of native celluloses of such solutions by using absolute methods and the intrinsic viscosity number [43]. The system anhydrous nitric acid in dichloromethane also allows the application of such polymer analogous reactions at temperatures between 0 and −30 °C [44]. Other authors [45] prefer the system nitric acid/phosphoric acid/phosphorus pentoxide.

Nitration in the Laboratory. Preparative cellulose nitration with HNO_3/H_2SO_4 nitrating acid to products with whatever N content up to 13.65 % is desired, stabilization and stabilization tests, nitration with the nitric acid/phosphoric acid (< 13.9 % N) and nitric acid acetic anhydride systems up to the trinitrate, denitration with hydrogen sulfide to cellulose II, the analytic determination of the N and sulfate content, and the solution of the CN and the viscosity determination of the solution are extensively described in [46].

1.2.5. Commercial Types and Grades

Cellulose nitrates receive, because of their fluffy structure and cottonlike appearance, the additional designation "cotton."

Two parameters are decisive for the industrial use of cellulose nitrate:

Nitrogen content (including the resulting solubility properties)
Viscosity

As seen in Table 6, cellulose nitrates with differing nitrogen contents have various applications. Cellulose nitrates for lacquers are available in numerous viscosities. It is possible to categorize all stages of viscosity according to the European norm (DIN 53179), but the viscosity of cellulose nitrates is primarily categorized by using the Cochius method and the British or American ball drop method (ASTM D 1343-69).

In addition to the so-called cotton types densified CN types are available. These may be obtained by either nitrating compressed cellulose or by subsequently compressing the fluffy cellulose nitrate. It is possible to almost double the bulk density by compression.

For safety reasons, the commercially available CN cotton types must be wetted with at least 25 wt % water or aliphatic alcohols. In addition to water, ethanol, *n*-butanol, and 2-propanol may also be used as wetting agent.

Table 6. Cellulose nitrate types

Type	N content, %	Degree of substitution (DS)
Celluloid cotton	10.5 – 11.0	1.82 – 1.97
Alcohol-soluble >lacquer cotton	10.9 – 11.3	1.94 – 2.06
Lacquer cotton moderately soluble in alcohol	11.4 – 11.7	2.08 – 2.17
Ester-soluble >lacquer cotton	11.8 – 12.2	2.20 – 2.32
Powder cotton	12.3 – 12.9	2.55 – 2.57
Gun cotton	13.0 – 13.6	2.58 – 2.76

The largest manufacturers of cellulose nitrates are the following:

Hercules Inc.	USA
Wolff Walsrode AG	FR Germany
Hagedorn	FR Germany
WNC Nitrochemie GmbH	FR Germany
Société Nationale des Poudres et Explosifs (SNPE)	France
Imperial Chemical Industries (ICI)	Great Britain
S.I.P.E. Nobel S.p.A.	Italy
Unión de Explosivos Río Tinto S.A.	Spain
Bofors	Sweden
Asahi	Japan
Daicel Chemical Industries, Ltd.	Japan

Many countries in South America, Asia, and Eastern Europe maintain small CN production facilities. The total world capacity may be estimated to 150 000 t/a of dry cellulose nitrate.

Other Commercial Types. Also available, in addition to cellulose nitrate cotton types, are so-called cellulose nitrate chips, made from cellulose nitrate plasticized by gelatinizing softeners. For safety reasons, the softener content has been established at a minimum of 18 wt %. Chips are preferred in processes where alcohols interfere in the formulation of lacquers.

The dispersions of cellulose nitrate with softeners or resins in water manufactured by the Wolff Walsrode AG are other available forms. The solvent-free or low-solvent dispersions are not polluting and may be used in all areas in which cellulose nitrate lacquers also are used [55].

1.2.6. Analysis and Quality Control

The most important analytical characteristics relate to the determination of the N content and, thereby, the average degree of substitution (DS), as well as the viscosity of the solution as a measure of the average molecular mass or chain-length.

Analytic Tests. The most commonly used analytic procedures are summarized in [25], [46], [47], and [48].

Dry content is determined by careful drying of a small, thinly layered alcohol or water-wet sample at room temperature for 12 – 16 h, in a weighing glass at 100 – 105 °C for 1 h, or with compressed warm air at 60 – 65 °C for 0.5 – 1 h.

Ash content is determined by decomposing a dried sample with HNO_3 and incinerating the residue. Specifications require that the ash content should not be above 0.3 %.

N-content is determined by reducing nitrates according to the following reaction (Schulze-Thiemann):

$$NO_3^- + 3\,FeCl_2 + 4\,HCl \longrightarrow 3\,FeCl_3 + Cl^- + 2\,H_2O + NO$$

or by the following reaction:

$$2\,NO_3^- + 4\,H_2SO_4 + 3\,Hg \longrightarrow 3\,HgSO_4 + SO_4^{2-} + 4\,H_2O + 2\,NO$$

The resulting NO is collected in a Du Pont nitrometer.

Stability Tests [25]. *Deflagration Temperatures:* Well-stabilized CN deflagrates at temperatures above 180 °C.

Bergmann – Junk Test [29]: A quantity of 2 g of dried CN is kept at a temperature of 32 °C for 2 h in a special apparatus for the elimination reaction, after which time the amount of the developed nitrous gases (after reduction to NO) is determined. CN is stable according to this test if no more than 2.5 cm^3 of NO per gram is measured.

Warm Storage Test: A quantity of 5 g of dried CN is stored in a glass-stoppered tube at 75 °C. Note is then made when the first nitric oxide (red-brown gas) becomes visible. Well-stabilized CN can be stored at 75 °C for at least 10 days.

ASTM Stability Test [48]: After storage at 134.5 ± 0.5 °C the time is noted in which the nitrous gases discolor methyl violet test paper.

Viscosity. *Viscosity according to DIN 53179:* If CN is dissolved in acetone in the appropriate concentration, CN solutions meeting this requirement show a apparent dynamic viscosity of 400 ± 25 mPa · s in the ball drop viscometer according to Höppler (ball no. 4) at 20 °C (Table 7).

Cochius Viscosity [25]: The viscosity of the various cellulose types is measured in commonly used solvent mixtures:

A and AM types: butanol/ethylene glycol/toluene/ethanol in the following proportions 1 : 2 : 3 : 4

E types: butanol/butyl acetate/toluene in the following proportions 3 : 4 : 5

Dried CN is dissolved in varying concentrations depending on the type and the time which an air bubble requires to rise 500 mm between two calibrations in a 7 mm Cochius tube at 18 °C is measured in seconds. The Cochius seconds are converted to absolute viscosity units mPa · s by multiplying with the factor 3.64 mPa.

Figure 6. Degree of polymerization (DP) and technical viscosity ("ball drop" in seconds of a 12.2 % CN solution with 12 % N in acetone). DP = 170 × viscosity

Ball drop method according to ASTM [49]: Dried CN is dissolved according to its viscosity stage in 12.5, 20.0, or 25.0 % ethanol/toluene/ethyl acetate according to [48]. The

Table 7. Characterization of cellulose nitrates according to DIN 53179

A types	CN concentration, % (absol. dry)	AM types	CN concentration, % (absol. dry)	E types	CN concentration, % (absol. dry)
				E 1440	4
				E 1160	7
				E 950	9
				E 840	12
		AM 760	14		
		AM 750	15		
				E 730	15
		AM 700	17		
				E 620	21
				E 560	22
				E 510	24
A 500	27	AM 500	27

				E 375	32
		AM 330	36	E 330	34

drop time of the balls with a diameter between 1/4 and 1/16 in. at 25 °C is given in seconds or converted into Pa · s. Figure 6 shows the relationship between the degree of polymerization and the technical viscosity (fall velocity of the balls in a 17.2 % CN solution in acetone).

Comparative viscosity charts for converting the various viscosities and comparing the various types are found in [25].

Solubility and Color. The color and cloudiness of solutions produced according to [48] are tested visually. Consistency, appearance, and depth of color can be controlled according to [50].

Dilution with Toluene. Toluene is added to a 12.2 % CN solution in butyl acetate at 25 °C until CN continuously precipitates. The dilution factor is noted. The dilution ratio of CN solutions with other solvents and blending agents is determined according to [51].

Film Test. The solutions made according to [48] are diluted with an equal volume of butyl acetate and poured as a film onto a glass plate. The dried films are examined for undissolved particles, surface structure, transparency, and gloss.

1.2.7. Uses

Explosives. Explosives may be categorized according to their use:

blasting agents
propellants and shooting agents
detonating agents
igniting agents
pyrotechnical agents

Cellulose nitrates are used primarily as propellants and gun powder, whereby the following distinctions can be made: *monobasic powder,* which is based solely on cellulose nitrate; *dibasic powder,* which contains further energy carriers such as, for example, nitroglycerin or diglycol dinitrate in addition to cellulose nitrate; *tribasic powder,* which contains in addition to the components of the dibasic powder a third agent such as nitroguanidine.

The selection of the cellulose nitrate is of special importance. The types of cellulose nitrates that differ in the degree of nitration were standardized as follows:

CP I (Collodium powder) also known as guncotton, nitrogen content: 13.3 – 13.5 %
CP II (Collodium) nitrogen content: 12.0 – 12.7 %, mostly 12.6 %
PE (Powder standard) nitrogen content: 11.5 – 12.0 %, mostly 11.5 %

Aromatic amines, such as diphenylamine, are added to gunpowder as stabilizers. They are capable of binding the nitrous gases generated during the decomposition of the nitric acid ester. A mixture of ca. 80 % highly nitrated gunpowder (13.4 % N) and ca. 20 % less-nitrated collodium cotton (12.5 % N) is used for the production of the monobasic propellant powder. Since cellulose nitrate granules are easy to charge electrostatically, they are made conductive with a fine graphite coating.

The multibasic powders usually contain cellulose nitrate CP II. Mixtures of 40 % PE cotton and 60 % CP I are also used because they have the same energy content as CP II with 12.6 % N.

The introduction of a third component to tribasic powder results in a lower heat of combustion in comparison to dibasic powder, thereby lengthening the life of the gun barrel.

Gunpowder is used in small-arms ammunition as well as large-caliber guns and tanks. (For further details → Explosives.)

Lacquers. Cellulose nitrate lacquers are characterized by the outstanding film-forming properties of the physically drying cellulose nitrate. Moreover, cellulose nitrate is compatible with many other raw materials used in lacquers and can be used advantageously in combination with resins, softeners, pigments, and additives.

In addition to the nonvolatile lacquer components, the composition of the solvent mixture is decisive for the formation of a film.

The most important uses for nitro lacquers are as follows: wood lacquers (especially furniture lacquers), metal lacquers, paper lacquers, foil lacquers (also as hot sealing lacquers, e.g., cellophane, plastic, and metal foils), leather lacquers, adhesive cements, putties, and printing ink (for flexo and gravure printing).

The processes used for applying cellulose nitrate lacquers to substrates are as follows: spraying (compressed-air, airless, and electrostatic spraying), casting (for example, with a curtain coater), rolling (especially for the application of small amounts of lacquer), doctor knife coating, and dipping.

The casting and rolling processes are used for lacquering large, even areas. Irregularly shaped objects are sprayed. The choice of a suitable type of cellulose nitrate (e.g., completely or moderately soluble in alcohol, soluble in esters, degree of viscosity) is dependent on the lacquer type. A highly viscous cellulose nitrate type is used if elastic and thin applications are desired (e.g., leather). However, if hard and thick layers are desired, low-viscosity types are preferred.

The concentration or the degree of viscosity of the cellulose nitrate determine the viscosity of the lacquer solution. However, the formulation of the lacquer must be taken into consideration when the mode of application is chosen. For example, a highly viscous dipping lacquer cannot be sprayed or casted.

Furthermore, the striking differences between ester-soluble and alcohol-soluble types should be taken into consideration when nitro lacquers are formulated (Table 8).

For further information on the formulation of cellulose nitrate lacquers, see [52], [53], and also → Paints and Coatings.

Dispersions. Conventional cellulose nitrate lacquers contain between 60 and 90 % organic solvents, which are released during drying. For economic and environmental reasons, it is desirable to substitute organic solvents by water. Aqueous cellulose nitrate/softener dispersions (e.g., Isoderm, Bayer AG; Coreal, BASF; Waloran N, Wolff Walsrode AG) are available for such absorbing substrates as leather [54]. Other aqueous cellulose nitrate dispersions for use on wood, foil, and metal have also been developed (Waloran N, special-types, Wolff Walsrode AG) [55]. The film forming process of water-insoluble cellulose nitrate requires a small amount of coalescents in the dispersion systems.

Celluloid. A special use of cellulose nitrate is in the production of celluloid [56]. Cellulose nitrate with a nitrogen content of 10.5 – 11.0 % is mixed in a kneader with softeners, particularly camphor, and solvents (alcohols).

Normal celluloid contains ca. 25 – 30 % camphor and 70 – 75 % cellulose nitrate. Celluloid that contains 10 – 15 % solvent can be formed into the desired articles in heated piston or screw presses (e.g., tubes and round and profile rods).

In the past decades, celluloid has been widely replaced by synthetic materials and thermoplastics. Celluloid is still of economic importance in the following areas: combs and hair ornaments, toilet articles, office supplies (drafting and measuring instruments), ping-pong balls, and various special uses.

1.2.8. Legal Provisions

Toxicology and Industrial Safety. Concentrated sulfuric acid, nitric acid, and nitrous gases formed during the production of cellulose nitrate are considered hazardous chemical products [57]:

Table 8. CN lacquer cottons

Ester-soluble type	Alcohol-soluble type
Possible use of alcohol in the lacquer formulation	Use of alcohol, especially ethanol, in any desired amount as a solvent
Good dilutability with aliphatic and aromatic hydrocarbons	Good dilutability with aromatic hydrocarbons
Very rapid solvent release	Rapid solvent release
Formation of hard films	Formation of films with thermoplastic properties
Attainment of good mechanical properties as far as the cold-check test, stretch, hardness, and tensile strength are concerned	Attainment of good mechanical properties; some special problems of lacquer production may be solved such as: Lacquers which can be diluted with ethanol in any desired manner (wood polishes) Odorless lacquers (printing inks) Gel dipping lacquers Hot sealing waxes (cellophane lacquers and aluminum foil lacquers)

1) Sulfuric acid
   5 – 15 % EC-No. 016-020-01-5
   above 15 % EC-No. 016-020-00-8
2) Nitric acid
   20 – 70 % EC-No. 007-004-01-9
   above 70 % EC-No. 007-004-00-1
3) Nitrous gases
   EC-No. 007-002-00-0

They are subjected to the Arbeitsstoffverordnung (working substance regulation) [58] and must, therefore, be adequately labeled.

Concentrated nitric acid and mixed nitrating acids are oxidizing when brought into contact with organic materials [59]. The MAK values (maximum working place concentration) are as follows:

nitric acid vapors: 10 mL/m^3 (ppm); $\triangleq$ 25 mg/m^3

nitrogen oxides (NO_2): 5 mL/m^3 (ppm); $\triangleq$ 9 mg/m^3

Employees should be examined regularly for obstructive respiratory tract illnesses.

Cellulose nitrate is neither toxic nor hazardous to health [60]. Damping agents in CN and nitrous gases which may be formed during combustion and smoldering processes are potentially hazardous to health if inhaled.

Commercially available phlegmatized cellulose nitrate for the production of lacquer with less than 12.6 % N contains at least 18 % of a gelatinizing softener. According to the first paragraph in [58], cellulose nitrate is a hazardous substance and must be packaged and labeled accordingly. EEC regulations (1982) are similar.

Damping agents such as ethanol and 2-propanol are not subjected to these regulations; butanol belongs to category II d, but is not considered to be hazardous to health in a damped mixture of a maximum 35 % concentration.

Storage and Shipping. Cellulose nitrate, especially guncotton, burns in air with a yellow flame and deflagrates if present in larger quantities, especially after rapid heating. An explosion can be caused by friction or a sharp impact. Dry CN has electrostatic charge. Friction, particularly on metals but also on plastics, can cause sparks which lead to a deflagration. Therefore, cellulose nitrate should be stored in a moist and cool place [60], [61]. Rooms in which cellulose nitrate is processed must be adequately protected according to the guidelines for protection from explosions.

Cellulose nitrate is subjected to the regulations governing explosives [62]. The transportation of phlegmatized cellulose nitrates proceeds according to the most recent versions of the hazardous materials regulation; see [25]. Wetted cellulose nitrate is shipped in thick-walled, galvanized, tightly closing iron or fiber drums which are adequately labeled.

Dried cellulose nitrate may not be shipped under any circumstances.

For further information on the properties, handling, storage, and transportation of hazardous goods, see also [63].

1.3. Other Inorganic Cellulose Esters

Summaries on the esterification products of cellulose with other inorganic acids may be found in [12–19]. For publications on the modification of cellulose, including esterification, see [64].

1.3.1. Cellulose Sulfates

Cellulose sulfates [*9032-43-3*] are the most frequently investigated of all other inorganic cellulose esters. The ability of concentrated sulfuric acid to dissolve cellulose, particularly in concentrations between 70 and 75 %, has been known since 1819. After precipitation immediately following dissolution, the cellulose contains little or no bound sulfate. An almost homogeneous esterification takes place only if the cellulose is left in a sulfuric acid solution over a longer period of time. However, the ester yield is very poor. The major portions of the reaction products consist of hydrolytically split decomposition products with a maximum degree of substitution of 1.5.

In their free acidic form, cellulose sulfates are fairly unstable and easily saponified. A semiester was developed in 1953 in the United States [65] in an esterification mixture consisting of 1 mol of cellulose with 20 – 30 % water, 3.5 – 15 mol of sulfuric acid, 0.3 – 1.0 mol of a primary or secondary C_3–C_5 alcohol, and an inert volatile organic solvent such as toluene or carbon tetrachloride (reaction temperatures between − 5 and − 10 °C). The product was soluble in hot or cold water, yielded relatively stable, clear, and highly viscous solutions, and was recommended for use as a thickener for aqueous systems (emulsion paints and printing inks, printing pastes for textiles, and food products), as well as for fat- and oil-proof finish, and as paper glue. This product, however, is of no economic importance.

Numerous attempts have been made to find improved preparation methods for water-soluble cellulose sulfates stable to saponification. Known reaction systems are summarized in a tabular overview [65]. The reaction of cellulose with sulfuric acid in organic solvents, especially in lower-mass aliphatic alcohols, gives by way of a heterogeneous reaction fibrous and water-soluble cellulose sulfates with a maximum DS value of 1. More highly substituted products are obtained by reaction with sulfuric acid/acetic acid anhydride (up to a DS value of 2.8) or esterification with chlorosulfuric acid in pyridine or formamide. The reaction with SO_3 only or in various organic systems yields trisubstituted products. The reaction mechanism may be described as the addition of the strongly electrophilic SO_3 to the hydroxyl groups with the succeeding disintegration of the intermediately formed oxonium ion.

$$\text{Cell–OH} + SO_3 \longrightarrow \left[\text{Cell–}\overset{\overset{H}{|}}{\underset{+}{O}}\text{–}SO_3^-\right] \longrightarrow \text{Cell–O–}SO_3^- + H^+$$

Completely water-soluble, highly viscous sodium cellulose sulfate semiesters are obtained in homogeneous systems by the reaction of cellulose nitrite [67]. The intermediate that is formed and dissolved, cellulose nitrite, is obtained in the N_2O_4/dimethylformamide system and is at the same time transesterified by the SO_3/DMF complex. Uniformly substituted cellulose sulfate with a range of DS values between 0.3 and 2.0 and solution viscosities up to 7 000 mPa · s (in 1 % solution) can be obtained by using this process [68]. Such transesterified products can be cross-linked by metal ions to form highly effective thickening agents for aqueous media [69].

Such processes have been further developed [66] and make interesting novel fields of application accessible as a result of the rheological and gel-forming properties of the Na cellulose sulfate semiester.

Mixed esters such as cellulose acetate sulfates, cellulose acetate butyrate sulfates [70], cellulose acetate propionate sulfate [71], and ethyl cellulose sulfates [70], [72] are described in the patent literature.

Being polyelectrolytes, cellulose sulfates form salts and have ion-exchanging properties; thus, they have been recommended for use as cation exchangers [64, p. 65], [73], [74].

1.3.2. Cellulose Phosphate and Cellulose Phosphite

Reaction of cellulose with aqueous phosphoric acid gives the following unstable addition compound: $3\,C_6H_{10}O_5 \cdot H_3PO_4$, from which the cellulose can be regenerated unchanged by reaction

with water. Cellulose phosphates [*9015-14-9*] with a low phosphorus content are obtained by reacting cellulose or linters with phosphoric acid in an urea melt [75]. Higher phosphorus contents and a lower degradation rate of the cellulose may be obtained with excess urea at reduced reaction time (ca. 15 min) and at high temperature (ca. 140 °C). Water-soluble cellulose phosphate with a high degree of substitution may be obtained from a mixture of phosphoric acid and phosphorus pentoxide in an alcoholic medium [76].

Phosphorylated cellulose fibers show increased swelling after partial hydrolytic degradation and transfer into the alkali salt form and were, therefore, suggested for use as adsorbents [77].

Cellulose phosphates with a 17 % phosphorus content (this represents about 3/4 of the maximal possible substitution of triphosphate with 23 % phosphorus) were already produced in 1933 by reacting cellulose with a mixture consisting of concentrated sulfuric acid and phosphoric acid in the presence of a weakly acidic catalyst [78].

Cellulose phosphites [*37264-91-8*] and cellulose phosphonates may be prepared by transesterification with alkyl phosphites. All cellulose esters containing phosphorus have fire-retarding properties [78] and have attracted some interest due to their ion-exchanging effect [74], [79], but are not yet industrially used.

1.3.3. Cellulose Halogenides

Various preparative methods are suitable for the synthesis of halogenated cellulose derivatives [64, p. 64]. Halogenation can be carried out by transesterification of such cellulose esters as tosylate, nitrate, and sulfate with hydrohalic acids [80]. Nucleophilic substitution proceeds considerably faster in homogeneous systems than in heterogeneous aqueous systems.

The Finkelstein transesterification process of cellulose nitrate with sodium iodide in anhydrous acetone leads to deoxyiodo cellulose. The reaction of cellulose with thionyl chloride, $SOCl_2$, in the presence of pyridine produced a monosubstituted, but strongly decomposed and unstable, hydrogen chloride ester.

Halogenation of cellulose improves its water-resistant and flame-resistant properties. Slight fluorination increases oil resistancy and lowers the soiling potential of cellulose textiles [64]. Commercial applications are not yet known.

1.3.4. Cellulose Borates

The preparation of cellulose borate succeeded by means of transesterification of methyl and *n*-propyl borate with cellulose [64, p. 7]. The products with a maximum DS value of 2.88 are, however, extremely sensitive to hydrolysis and alcoholysis.

1.3.5. Cellulose Titanate

Cellulose can be reacted to cellulose titanates in a heterogeneous reaction system by reacting it with titanium tetrachloride in DMF or with chlorinated anhydrides, chlorinated ester anhydrides, and esters of the hypothetical orthotitanic acid $Ti(OH)_4$ [81]. Ethyl trichlorotitanate has been shown to be the most reactive. Esters with 16 % titanium content are possible.

Cellulose esters with a titanium content between 3 and 5 % do not burn or smolder. They possess considerable hydrolytic stability in neutral and weakly alkaline media, but are easily hydrolyzed at a low pH.

1.3.6. Cellulose Nitrite

The nitrite of cellulose came of scientific and possibly practical interest as a cellulose derivative in 1974 [67]. It is obtained by reacting cellulose with nitrosyl compounds such as dinitrogen tetroxide, N_2O_4 (corresponding to nitrosyl nitrate), or nitrosyl chloride, NOCl, in dimethylformamide or dimethylacetamide as a proton acceptor and solvent for the resulting ester. The reaction proceeds in a homogeneous phase to the trinitrite.

Cellulose nitrite is extremely sensitive to hydrolysis. Chain degradation to a DP of 200

(level-off DP) was observed to take place within 3 h in the presence of water. The scientific and preparative importance of cellulose nitrite is based on its high reactivity, which may be used to produce many other cellulose esters, also mixed esters, by transesterification in a homogeneous phase [82]. Transesterification to stable cellulose sulfates has already been mentioned [67]. In this manner, water-soluble cellulose nitrates with a DS value of 0.5 – 0.6 may also be obtained [83].

Cellulose solutions produced under cold conditions (up to ca. 5 °C) in a N_2O_4/DMF system are relatively stable to degradation and can be produced, depending on the DP of the cellulose, up to a concentration of 14 %. The cellulose can be regenerated in an unaltered form to cellulose II, with the result that this process has already been considered as an alternative to the environmentally detrimental viscose process [84]. Not only an attempt was made to achieve good mechanical textile properties from the regenerated fibers, but also to recycle the expensive solvent. An economic solution to the competition with the viscose process has not yet been found.

1.3.7. Cellulose Xanthate

Cellulose xanthate [*9032-37-5*], an important intermediary molecule for the production of regenerated cellulose according to the viscose process (see Cellulose, Chap. 3.1.1.), must also be considered as an ester of an inorganic acid, namely the nonexistent thiol – thion carbonic acid.

The O ester of this compound with organic residues is the xanthic acid and the appropriate salts. Sodium cellulose xanthate is obtained by reacting alkali cellulose with carbon disulfide, which dissolves in dilute sodium hydroxide to an orange-yellowish, highly viscous solution, the so-called viscose.

The regenerated cellulose is precipitated in the form of fibers (rayon, cord, and rayon staple), foils (cellophane), or tubes in precipitation baths containing sulfuric acid and salts (see → Cellulose, Chap. 3.1.3.). About 4×10^6 t of regenerated cellulose is presently produced worldwide by using the viscose process.

For further information, see → Cellulose, Chap. 3.

2. Organic Esters

Cellulose can theoretically form an unlimited number of organic acid esters because of its anhydroglucose units with three reactive hydroxyl groups each. Industrial possibilities are, however, drastically limited by the complex nature of the cellulose molecule. Highly esterified organic esters are, therefore, only produced from a few aliphatic fatty acids with up to four carbon atoms.

Cellulose acetate [*9004-35-7*], cellulose acetate propionate [*9004-39-1*], and cellulose acetate butyrate [*9004-36-8*], which have been known for quite some time and are in large-scale production, are especially important esters. Formic acid esters are, because of their instability, of no industrial importance.

Only cellulose acetate phthalate [*9004-38-0*] has found limited use as a tablet coating; all the other described cellulose esters such as cellulose palmitate, cellulose stearate, esters of unsaturated acids such as crotonic acid, or esters of dicarboxylic acids are not used industrially.

Historical Aspects. Cellulose acetate was first synthesized by P. Schutzenberger in 1865 by heating cellulose and acetic acid under pressure, whereby a product of very low molecularity was obtained. In 1879, A. P. N. Franchimont added sulfuric acid to the esterification process, which remains to this day the most frequently used catalyst. The limited solubility of cellulose acetate in less-expensive solvents and poor compatibility with the then-known softeners was a considerable obstacle for its industrial use. The problem was solved in 1904 when F. D. Miles and A. Eichengrün simultaneously succeeded in synthesizing an acetone-soluble secondary acetate by partially hydrolyzing a primary triacetate.

During World War I, the less-flammable airplane paints based on cellulose secondary acetate reached considerable importance as a re-

placement for nitrocellulose. At almost the same time, the manufacture of foils, films, synthetic silk, and plastic masses developed.

An especially high number of publications and patents were achieved between 1920 and 1935. Ultimately, only a few processes proved to be industrially useful, most of which are still used today.

Even though the technology of cellulose ester production is considered for the most part to be complete, research continues in the fields of rationalization and improvement of production methods, leading to products with greater uniformity and improved properties, as well as in the development of new fields of application, especially with the introduction of cellulose acetate propionate and cellulose acetate butyrate.

2.1. Cellulose Acetate

2.1.1. Chemistry of Cellulose Esterification

The esterification reaction of the primary and secondary hydroxyl groups of cellulose does not basically differ from that of other alcohols. The peculiarities lie in the macromolecular structure of the cellulose molecule. The splitting of the molecule chain competes with the catalyzed esterification, but can be fairly well controlled under appropriate conditions. The speed and completeness of the reaction is dependent on the quality of the cellulose, whereas the different reactivities of the primary and secondary hydroxyl groups [83], [86] have little influence on industrial processes.

Acids, acid chlorides, and acid anhydrides are possible *esterification reagents* for the three hydroxyl groups in each glucose unit.

Esterification with free acids, with the exception of formic acid [87], whose esters are not stable, requires such high temperatures and catalyst concentrations that only low molecular mass products are obtained. Acid chlorides in pyridine, however, were suggested for use in the production of esters from higher fatty acids (lauric acid, stearic acid, and palmitic acid), without ever having attained any industrial significance. Attempt was made to manufacture cellulose acetate industrially with acetyl chloride and catalysts, but the process proved to be useless.

All industrial processes in current use, therefore, are based on acetic acid anhydride as a reactant, whereby theoretically 3 mol of anhydride per unit of glucose are used and 3 mol of acetic acid are formed.

Attempts to use ketene, which could be directly accumulated without incurring acetic acid, which must again be processed, did not lead to any results [88].

Numerous *catalysts* were suggested to accelerate the reaction. Only sulfuric acid and perchloric acid are of any practical importance. Zinc chloride, which is required in large amounts of 0.5 – 1 part per part of cellulose, is no longer used today because of the high reprocessing costs. Other mineral acids, however, are not sufficiently acidic in the water-free acetic acid – acetic acid anhydride system. The catalytic effect of sulfuric acid is primarily in the rapid and quantitative formation of acidic cellulose – sulfuric acid esters (sulfoesters) [89], which are substituted by acetyl groups as the reaction progresses and the temperature rises.

Due to the topochemical character of the reaction, soluble cellulose esters with low acetic acid content can be obtained only from the triester stage by way of hydrolysis. Incompletely esterized and insoluble derivatives are found in addition to the triester before completion of the reaction.

Cellulose esters with low acetic acid content are produced by subsequent *hydrolysis* in a homogeneous system by adding water or dilute acetic acid to destroy the excess anhydride and possibly by adding sulfuric acid for acceleration and then again split off under controlled conditions (temperature, water content, and time) a certain number of acetyl groups without further breakdown of the cellulose chain.

2.1.2. Raw Materials

Cellulose. The production of high-quality cellulose esters requires that special attention be paid to the selection of the starting materials. The cellulose bases generally consist of highly purified cotton linters with an α-cellulose content of over 99 % and celluloses from wood pulp which contain between 90 and 97 % α-cellulose.

After the long layered spinnable cotton has been freed of the cotton seed by ginning, the remaining shorter fibers on the seed pod are usually removed with two cuts before the seeds go to the oil presses for further processing. The first cut gives about 4 % longer linters relative to the entire cotton flower, which are preferentially processed to medicinal cotton, felt, paper, etc. The second cut gives about 8 % shorter layered linters, which are best suited for further chemical processing.

The raw linters undergo mechanical cleaning by means of screening, pressure boiling in a 3 – 5 % sodium hydroxide solution, and finally acid – alkaline bleaching. Special care should be taken during drying, since local overdrying of cellulose, the water content of which should lie between 3 and 8 %, impairs the reactivity considerably. Table 9 shows analytical values of good linters [90].

Table 9. Analytical values obtained from bleached linters according to [90]

α-Cellulose	99.7 %
β-Cellulose	0.2 %
γ-Cellulose	0.1 %
Carboxyl groups	<0.02 %
Total ash	0.02 %
Degree of polymerization	1000 – 7000

For a long time, cellulose from wood pulp could only be used for the manufacture of lower-quality cellulose esters because of the 90 – 95 % α-cellulose content. Celluloses with an α-cellulose content of 96 % have been available since about the 1950s. Due to special processing techniques, they give cellulose esters comparable to those produced from linters as far as tensile strength, color, clarity of the solutions, and light stability as well as thermal stability are concerned.

Acetic Acid Anhydride. Most manufacturers of cellulose acetate convert the resulting acetic acid to anhydride directly on the premises and adjust the concentrations as required for their process, generally between 90 and 95 %.

2.1.3. Industrial Processes

Only a few of the proposed industrial processes for the manufacture of cellulose esters have attained industrial significance. Even when the fact that no two manufacturers use identical processes is taken into consideration, the following categories can be distinguished:

1) Acetylation in a homogeneous system (solution acetate)
   - Use of glacial acetic acid as a solvent (glacial acetic acid process)
   - Use of methylene chloride as a solvent (methylene chloride process)
2) Acetylation in a heterogeneous system (fiber acetate)

Whereas the triester that is formed during esterification according to the solution acetate process goes into solution and can subsequently be hydrolyzed to secondary acetate, fiber acetate is formed in the presence of nonsolvents, similar to the nitration of cellulose. This method does not permit hydrolysis.

A flow diagram of the entire process is shown in Figure 7.

2.1.3.1. Pretreatment

The cellulose is first dried to obtain a moisture content of 4 – 7 %. Too little moisture would lower the reactivity of the cellulose, and too much moisture would lead to a higher acetic acid consumption and an extremely violent reaction start.

Acetic acid is generally used as a pretreatment reagent, which for some processes can contain small amounts of sulfuric acid to further improve the diffusion of the acetylating reagents. It is believed that the pretreatment process causes a partial swelling of the cellulose by splitting the hydrogen bonds so that the acetylating reagents can enter the fibers more rapidly.

A ratio of 30 – 100 parts of glacial acetic acid per 100 parts of cellulose, which is sprayed into the thoroughly mixed cellulose at temperatures

Figure 7. Flow chart for the production of cellulose esters according to [91]
a) Acid reconditioning; b) Acidanhydride; c) Esterification; d) Hydrolysis; e) Precipitation; f) Washing; g) Centrifuge; h) Drier; i) Evaporator; k) Azeotropic distillation; l) Cooler; m) Decanter

of up to 50 °C in appropriate equipment such as mixing vats, is usually sufficient for the pretreatment process. Pretreatment, depending on the process and temperatures, takes from one to several hours.

2.1.3.2. Esterification

Acetic Acid Process. The acetylation mixture consists of glacial acetic acid as a solvent for triacetate, an excess of 10 – 40 % glacial acetic acid anhydride and, depending on the process, 2 – 15 % sulfuric acid with respect to the cellulose.

Esterification begins after the initial spontaneous reaction of the water contained in the cellulose with part of the anhydride; the semiliquid mass uniformly saturated with acetylation mixture forms a fiber pulp while developing temperatures of up to 50 °C and ultimately a highly viscous solution.

A decomposition of the cellulose chain takes place parallel to the strongly exothermic esterification. The chain degradation can be controlled by controlling the reaction temperature, e.g., by adding cooled solution portionwise and cooling the reaction vessel down to the desired temperature range. The use of glacial acetic acid as a solvent, in which the highly esterified triacetate is poorly dissolved, results in gel formation and precipitation of the triacetate. This is due to the formation of sulfate acetate, which is formed as an intermediate during the reaction. It is reesterified to pure acetic acid esters especially at higher temperatures.

After the reaction solution is free of fibers, the degradation of the cellulose ester molecule can continue until the desired viscosity is attained. The reaction is then stopped by adding water or dilute acetic acid, which destroys the excess anhydride.

Cooled kneaders are suitable reaction vessels in that they allow a rapid and uniform mixture and catalyst distribution through intensive mixing. This is important for controlling the reaction (Fig. 8).

Methylene Chloride Process. Using methylene chloride (*bp* 41 °C) as a solvent presents several advantages over acetic acid. Due to the fact that methylene chloride is such an excellent solvent for primary triacetate, lower catalyst concentrations (1 % sulfuric acid) are required at higher esterification temperatures. Furthermore, due to its low boiling point, the heat of reaction can be removed by means of vaporization and return of the cooled methylene chloride. The reaction of highly viscous solutions can, thus, be better controlled. Finally, only a half to a third as much dilute acetic acid must

be recycled compared with the glacial acetic acid process.

Table 10. Acetylating preparations according to the glacial acetic acid process and the methylene chloride process [92]

	Acetic acid process	Methylene chloride process
Cellulose	700 kg	3 500 kg
Pretreatment	700 kg glacial acetic acid	1 200 kg glacial acetic acid
Acetylation	1 900 kg anhydride	10 500 kg anhydride
	4800 kg glacial acetic acid	14000 kg methylene chloride
	50 kg sulfuric acid	35 kg sulfuric acid

Table 10 shows typical examples for acetylation according to the glacial acetic acid and methylene chloride processes. Figure 9 shows a sceme for the production of cellulose acetate according to the methylene chloride process.

Acetylation according to the methylene chloride process is carried out largely in rotating drums (roll vats) or in horizontal containers with shovel-like stirrers on both sides. The problem of corrosion, which arises during esterification and especially during hydrolysis, has only been

partially solved by using equipment constructed of bronze, high-alloy steels, or plates containing metals such as silver, titanium, or tantalum.

Fiber Acetate. Cellulose can be esterified maintaining its fiber structure by adding sufficient amounts of nonsolvents to the triacetate during acetylation. Carbon tetrachloride, benzene, or toluene can be used as nonsolvents [94], [95].

Figure 10. Acetylation equipment for cellulose triacetate fibers [92]
a) Perforated drum; b) Reaction solution; c) Cellulose fibers; d) Cooler for acetylating liquid; e) Acetylating liquid circulation

Temperature and catalyst concentrations are similar to those required for the solvation process. A large amount of liquid is required to keep the loose voluminous cellulose in suspension. Perchloric acid is preferred as a catalyst because of the great difficulty with which the sulfuric acid ester is split in this system.

The hydrolysis of fiber acetate to acetone-soluble esters is not possible in a heterogeneous system. Its utilization is limited to special applications, such as the manufacture of foils and films from triacetate.

As shown in Figure 10, fiber acetate is produced by rotation in various directions and at various speeds in a perforated drum enclosed in a metal casing. The shaft of the drum is hollow so that liquid may be added during rotation [96].

Continuous Processes. In spite of numerous attempts, continuous acetylation and hydrolysis processes have achieved only limited industrial applications and are not used in the production of high-quality esters for, among others, plastic masses. Due to the varying reactivities of the different celluloses, considerable variations between batches are possible so that the development of a continuous process is seriously impeded.

2.1.3.3. Hydrolysis

After the esterification is completed, the process is interrupted by adding water or dilute acetic acid. Sufficient water must be added to decompose the excess anhydride and adjust the water content of the solution to 5 – 10 % so that, aside from hydrolysis, no further decomposition of the molecular mass occurs, but at the same time the bound sulfuric acid is almost completely split off. The speed of hydrolysis depends on the temperature, which – depending on the process – ranges between 40 and 80 °C, and on the amounts of sulfuric acid and water.

The course of hydrolysis is constantly monitored by checking the solubility of the secondary acetate. The reaction is terminated at the desired degree of substitution by neutralizing the catalyst, preferably with sodium acetate or magnesium acetate. The proportion of free hydroxyl groups in the ester should be maintained as reproducibly precise as possible because it determines the properties and the utilization of the ester.

2.1.3.4. Precipitation and Processing

The product precipitates in the form of flakes or powder during intense stirring after water or dilute acetic acid has been gradually added. The methylene chloride process requires that the methylene chloride be completely distilled before precipitation occurs. A part of the precipitating acid is added to the solution to just before the point of precipitation when the main portion of the acid is added. The process must be carefully monitored to achieve a product with an open structure which can be easily rinsed out. The precipitate can be broken down and thoroughly rinsed, whereby the dilute acid is brought back into the cycle. Rinsing is done primarily by using continuous methods based on the countercurrent principle (Fig. 9).

High-quality products for plastic masses are stabilized and bleached. Bound sulfuric acid

remnants are removed by either boiling under pressure or heating in 1 % mineral acids during stabilization.

After further rinsing and removal of excess water by suctioning or by thrust extraction, the product is carefully dried, preferably in a vacuum shovel drier, to a water content of < 1 – 3 %.

The cellulose acetate yield from a good process is at least 95 % of the theoretical yield.

Major manufacturers of cellulose acetate are the following (1971) [103]: Bayer AG, Leverkusen; British Celanese Ltd., London; Celanese Corp. of America, New York; Courtaulds Ltd., Manchester; Daicel Ltd., Osaka, Japan; E. I. DuPont de Nemours & Co., Inc., Wilmington; Eastman Kodak Comp., Kingsport; UCB Fabelta, Tubize, Belgium; Gevaert-Agfa, Antwerp; Hercules Powder Comp. Ltd., London; Rhodiaceta, Lyon; Soc. Rhodiatoce SpA, Milan; Rhône-Poulenc, Paris; VEB Orbitaplast, Eilenburg, GDR.

A number of products are further processed to fibers, films, or injection-molding compounds in the manufacturers' own facilities and never reach the market as a raw material.

2.1.4. Recovery of Reactants

The recovery of the incurred large amounts of acetic acid is a decisive factor for the profitability of a process.

Recovery of Acetic Acid. Depending on the process, 2 – 6 parts of 15 – 25 % dilute acetic acid per part of cellulose accumulate. They must be reprocessed to glacial acetic acid and acetic acid anhydride.

Only continuous processes consisting of a combination of extraction and azeotropic distillation are of practical importance. The dilute acid is, for example, extracted with ethyl acetate in a countercurrent and is subsequently distilled, so that 99.8 % pure glacial acetic acid can be removed from the bottom of the column while the azeotropic ethyl acetate water is removed from the top.

Recovery of Acetic Acid Anhydride. Since only a portion of the accumulated glacial acetic acid is required for the acetylation process, the remainder must be converted to glacial acetic acid anhydride.

The ketene process developed by the Wacker Co. (→ Acetic Anhydride, Chap. 1.3.1.1.) is in general use [97]: Pure, almost anhydrous glacial acetic acid is continuously vaporized under a vacuum and is split to ketene in the presence of small amounts of the catalyst triethyl phosphate; ketene then reacts with glacial acetic acid to form the anhydride (→ Acetic Anhydride, Chap. 1.3.1.2.).

Recovery of Methylene Chloride. Methylene chloride can be recovered inexpensively because of its insolubility in water, which allows its recovery from the raw solution without further processing steps in almost pure form.

2.1.5. Properties of Cellulose Acetate

Table 11. Physical characteristics of cellulose acetate [90], [92], [98]

Characteristic	Triacetate	Secondary acetate
Density, g/cm^3	1.27 – 1.29	1.28 – 1.32
Thermal stability, °C	>240	ca. 230
Tensile strength of fibers, kg/mm^2	14 – 25	16 – 18
Tensile strength of foils		
longitudinal, kg/mm^2	12 – 14	8.5 – 10
transverse, kg/mm^2	10 – 12	8.5 – 10
Refractive index of fibers toward the fiber axis

10^6 Hz		0.026
Specific resistance, $\Omega \cdot$ cm	$10^{13} - 10^{15}$	$10^{11} - 10^{13}$
Specific heat, J g^{-1} K^{-1}		1.46 – 1.88
Thermal conduction, J m^{-1} h^{-1} K^{-1}		0.63 – 1.25

Cellulose acetate and the other fatty acid esters are white, amorphous products that are commercially available as a powder or flakes. They are nontoxic, odorless, tasteless, and less

flammable than nitrocellulose. They are resistant to weak acids and are largely stable to mineral and fatty oils as well as petroleum.

Some physical characteristics are given in Table 11.

Properties and applications of cellulose acetates are primarily determined by the following:

1) viscosity of their solution
2) degree of esterification or the amount of bound acetic acid

*Viscosity*as an indicator for the degree of polymerization influences to a great extent the mechanical properties of the resulting fibers, films, or plastic masses, as well as their workability.

The *degree of esterification* primarily determines the solubility and compatibility with softeners, resin, varnish, etc., and ultimately also influences the mechanical properties.

Figure 11. Solubility of cellulose acetate in various solvents (abridged according to [99])
∗ Technical grade

The wide span of solubility properties of hydrolyzed cellulose acetate is shown in Table 12.

The compatibility of the plasticizer and the solubility in polar solvents increase with decreasing acetic acid content while the solubility in nonpolar solvents decreases. Moreover, a correlation between the incompatibility with nonsolvents such as water, alcohol, benzene, or toluene and a decreasing degree of esterification exists. Furthermore, a number of solvent combinations are known which are able to dissolve the cellulose acetate although each of the components is a nonsolvent.

Figure 11 shows a selection of solvents for the industrially interesting range of esterification (52 – 62 % bound acetic acid). Detailed information on solubility and softener selection can be found in the literature and the manufacturers' information brochures.

2.1.6. Analysis and Quality Control

The *viscosity* is determined in practice by the usual methods. Along with the relative viscosity, the measurement of 15 – 20 % solutions according to the ball drop method corresponding to ASTM 871-56 has been generally accepted.

The *acetic acid content* is generally determined by saponification of the ester with 0.5 N-potassium hydroxide and back-titration of the excess. The free acids from mixed esters are separated from the residue after saponification by means of distillation or extraction and by extraction or azeotropic distillation isolated and titrated. Gas-chromatographic methods have found increasing popularity. A comprehensive presentation can be found in [100], [101].

Determination of the *free hydroxyl groups* in pure cellulose acetate is not necessary, since a precise analysis of bound acetic acid is possible. It is primarily used to characterize the mixed esters and can be carried out according to various methods. Complete esterification with acetic acid anhydride in pyridine and back-titration of the excess is a proven method [102]. The value is mostly given as a percentage of the hydroxyl or as the hydroxyl value (mg of KOH/g).

Additional quality control methods for unprocessed cellulose esters are the following: determination of temperature stability by heating to 220 – 240 °C and evaluation of discoloration and melting behavior, the determination of free acid as an indicator for the efficacy of the rinsing process, and determination of the ash content as well as clarity, color, and filterability of the solution.

Table 12. Solubility of cellulose acetate at various degrees of esterification [91]

Degree of esterification	Bound acetic acid	Chloroform	Acetone	2-Methoxyethanol	Water
2.8 – 3.0	60 – 62.5 %	soluble			
2.2 – 2.7	51 – 59 %		soluble		
1.2 – 1.8	31 – 45 %			soluble	
0.6 – 0.9	18 – 26 %				soluble
<0.6	<18 %				

2.2. Cellulose Mixed Esters

Apart from the long-established cellulose acetate, only cellulose mixed esters of acetic and propionic acid, cellulose acetate propionate [*9004-39-1*], or acetic and butyric acid, cellulose acetate butyrate [*9004-36-8*], have attained any notable importance.

Mention should also be made of cellulose acetate phthalate [*9004-38-0*], which is used in certain special fields of application.

Pure cellulose propionates [*9004-48-2*] and cellulose butyrates [*9015-12-7*] are difficult to produce and – like formates, palmitates and stearates, and esters of unsaturated acids and dicarboxylic acids – have attained no industrial importance [4].

2.2.1. Production

As far as the chemistry of the esterification reaction and the subsequent partial saponification are concerned, the basic description given in the chapter on cellulose acetate is also valid for mixed acids to a large extent.

The raw materials used are the same as for cellulose acetate, i.e., cotton linters or cellulose produced by special processes.

Pretreatment of the cellulose raw materials is similar to that used in the production of cellulose acetate. In practice, esterification takes place only in a homogeneous system and not, as is sometimes the case with cellulose acetate, in a heterogeneous system. The esterification mix consists of a mixture of anhydrides of acetic acid and propionic acid or of acetic acid and butyric acid. The reactivity of the aliphatic fatty acids decreases very rapidly as the chain-length increases.

Mixed esters consisting of propionic acid and butyric acid or of acetic acid, propionic acid, and butyric acid are not produced on an industrial scale.

2.2.2. Composition

The properties of the mixed esters are determined not only by their viscosity, but also in particular by the ratio of the two bound acids and by the content of free hydroxyl groups.

At present, cellulose acetate propionate and cellulose acetate butyrate flake is only produced by two manufacturers: Bayer AG, Leverkusen, in the Federal Republic of Germany, and the Eastman Kodak Co., Kingsport, Tennessee, in the United States.

Whereas pure cellulose acetates are clearly characterized by their viscosity and content of bound acetic acid, with mixed esters, data on the individual acids and possibly the free hydroxyl groups are also required.

2.2.3. Properties

As the degree of hydrolysis changes, the properties of cellulose mixed esters vary over a wide range from pure acetates to pure butyrates, with the propionates occupying a property-profile position between the cellulose mixed esters and pure acetates.

In the case of cellulose acetate butyrate, for example, if one considers the mixing range from pure cellulose acetate through the various mixing ratios to pure cellulose butyrate (the degree of esterification is adjusted in such a way that the esters in pure cellulose acetate contain 50 – 60 % acetic acid, and those in pure butyrate 60 – 70 % butyric acid), then the density varies from ca. 1.32 (cellulose acetate) to 1.16 (cellulose butyrate). The melting point is between ca. 300 °C (cellulose acetate) and 160 °C (cellulose butyrate), while the water absorption at 90 % relative humidity varies from ca. 12 % (cellulose acetate) to 1.5 % (cellulose butyrate).

Solubility in various solvents (like acetone, methyl ethyl ketone, methyl isobutyl ketone, and various phthalate plasticizers) also varies over a wide range [104].

Typical examples of cellulose acetate propionates, whose acetic acid and propionic acid levels are practically identical, are given in Table 13.

With cellulose acetate propionates, the acetic acid content varies from ca. 3 to 8 %, and the propionic acid content from ca. 55 to 62 %. With cellulose acetate butyrates, acetic acid contents of 19 – 23 % and butyric acid contents between 43 and 47 % are normal.

There are many more grades of cellulose acetate butyrate available than of cellulose acetate propionate.

Examples of cellulose butyrate grades are given in Table 14.

2.2.4. Other Organic Cellulose Mixed Esters

Cellulose acetate phthalates are cellulose mixed esters of minor industrial importance. They are produced from hydrolyzed cellulose acetate by reaction with an excess of phthalic anhydride in acetone or dioxane [106].

This produces esters of phthalic acid with a free carboxyl group. The products are used on a small scale as water- or alkali-soluble textile auxiliaries, tablet coatings, and antistatic agents in film coating.

2.2.5. Uses

The wide scope of variation for cellulose esters has led to the development of special grades for different fields of application.

Mixed esters based on cellulose acetate butyrate and cellulose acetate propionate are chiefly used in the production of molding plastics (see Section 2.4). The applications described in the following are of lesser importance.

Films. Triacetate is more widely used than cellulose acetate butyrate as an electrical insulating film, which is mainly produced by casting. Cellulose acetate butyrates with an acetic acid/butyric acid ratio between 2 : 1 and 1 : 1 are preferred.

The importance of cellulose mixed esters as film substrates in the photographic industry has greatly diminished as a result of the increasing use of polyester film.

Surface coatings. Cellulose ester lacquers, with their excellent lightfastness, gloss, low combustibility, and good thermal stability, coupled with their indifference to hydrocarbons, oils, and greases, became very quickly established in numerous fields of application.

One significant step forward was the introduction of cellulose acetate butyrates and cellulose acetate propionates. Both are particularly characterized by lower water absorption and good compatibility with extenders and, in the case of the low-viscosity grades, also allow the production of very high-solid lacquers. Cellulose acetate butyrate has become particularly important as an extender for metal effect finishes [105].

2.3. Cellulose Acetate Fibers

Cellulose acetate is the most important cellulose ester. It is primarily used for textile yarn and cigarette filter tow. The cellulose acetate is usually dissolved in a suitable organic solvent and spun by dry spinning (→ Fibers, 3. General Production Technology). Secondary (2.5) acetate with an acetic acid content of 54 – 56 % is normally used, whereas only a small amount of cellulose triacetate is normally produced.

2.3.1. Properties

The viscosity and the filterability of the spinning solution (spinning dope) are particularly important in the production of cellulose acetate fibers. The spinning dope has a high viscosity, which depends on the degree of polymerization. The strength and stretch properties of the fibers also depend on the concentration and the degree of polymerization as well as on the distribution of the acetate groups along the cellulose chain.

Because the fibers are produced by extruding the spinning dope through minute spinnerette holes, insoluble particles must first be removed

Table 13. Characteristic data of cellulose acetate propionate (Cellit PR) [105]

	PR 900	PR 800	PR 500

Table 14. Characteristic data of cellulose acetate butyrate (Cellit BP) [105]

	BP 300	BP 500	BP 700/25	BP 700/40	BP 900
Acetyl content, %	14	14	15	14	15
Butyryl content, %	37	37	37	37	37
Hydroxyl content, %	1.2	1.2	0.8	1.2	0.8
Viscosity (DIN 53015), mPa · s	30 – 60	150 – 240	750 – 1500	750 – 1500	5000 – 8000
Melting range, °C	160 – 180	170 – 190	170 – 190	170 – 190	180 – 200

from the spinning dope by filtration. These particles are primarily composed of very small, incompletely acetylated cellulose fibers or gels, which can obstruct the spinnerett holes.

Secondary acetate and triacetate fibers have similar physical properties (Table 15). Their densities are lower than that of viscose rayon fibers and equal to that of wool. For textile yarns, the fibers should be as free of color as possible.

Table 15. Physical properties of acetate fibers and tow [107]

	Secondary acetate	Triacetate
Strength, cN/dtex	1.0 – 1.5	1.0 – 1.5
Stretch, %	25 – 30	25 – 30
Density, g/cm^3	1.33	1.30
Moisture uptake, % (65 % relative humidity, 20 °C)	6 – 6.5	4 – 4.5
Water retention capability, %	25 – 28	16 – 17
Melting point, °C	225 – 250	decomposition at 310 – 315
DP	300	300

The chemical reactions of cellulose acetate are similar to those of organic esters. Cellulose acetate is hydrolyzed by strong acids and alkali; it is sensitive to strong oxidizing agents but not affected by hypochlorite or peroxide solutions.

Acetate fibers cannot be dyed under the same conditions as viscose rayon fibers because their swelling properties are different. Acetate fibers can only be dyed with water-disperse dyes at the boiling point of the medium usually in the presence of carriers (→ Textile Auxiliaries). The carriers promote fiber swelling and enhance dye uptake by the fibers. The dyeing process coupled with the textile spinning operation assures color fastness. Triacetate fibers have better wash-and-wear properties than secondary acetate because of better dimensional stability and higher crease resistance.

2.3.2. Raw Materials

Table 16. Typical properties of acetate wood pulps

Characteristic*	Sulfite softwood pulp (conifer)	Sulfate hard-wood pulp (deciduous)
R_{10}, %	95	96
R_{18}, %	97	98
Ash, %	0.08	0.08
Silica, %	0.001	0.003
Calcium, %	0.006	0.008
Pentosans, %	1.2	1.2
Moisture content, %	6.5	6.5
Apparent density, g/cm^3	0.45	0.5
DP	2300	1700

* R_{10} and R_{18} are residues in 10 or 18 % sodium hydroxide at 20 °C [108]

Wood pulp produced from various softwood (conifer) or hardwood (deciduous) species is the cellulose source for the production of cellulose acetate fibers. The wood pulps are produced by the sulfite pulping process with hot alkali extraction or by the prehyrolized sulfate (Kraft) process with cold caustic extraction (→ Paper and Pulp). The lignins and hemicelluloses are removed from the wood to give wood pulps with an α-cellulose content of over 96 % (Table 16). High-purity cotton linters are no longer used in

the production of cellulose acetate fibers for economic reasons.

For the production of high-quality cellulose acetate fibers the wood pulp must have good swelling properties for uniform accessibility of the cellulose to the catalyst and the acetylation agent and a uniform reactivity. In addition, it must produce a spinning solution without fibers and gels which can easily be filtered.

2.3.3. Production

The general points discussed in Section 2.3.1 for the production of cellulose acetate also apply here. The sulfuric acid catalyst initially forms the cellulose sulfate ester. The sulfate groups are then replaced by acetyl groups as the acetylation proceeds. The sulfate ester contents is further reduced in the hydrolysis stage. However, any sulfate ester groups remaining at the end of the hydrolysis stage must be neutralized with an appropriate stabilizer, e.g., magnesium salts [109], [110]. Any "free" sulfate ester groups will affect the stability of the acetate because under the influence of heat and humidity they splitt off as sulfuric acid and degrade the fiber [111].

For secondary acetate spinning, acetone is used as the solvent. For triacetate, the solvent is 90 % dichloromethane and 10 % methanol or acetic acid (wet-spinning process). The viscosity of the spinning solution with a cellulose acetate concentration of 20 – 30 % is between 300 and 500 Pa s at 45 – 55 °C. The spinning dope is filtered in one or more steps and is then deaerated in large vessels.

Dry spinning is used almost exclusively; wet spinning is occasionally used for triacetate only. The spinneretts for textile filament have between 20 and 100 holes and those for tow up to 1 000. The fibers are formed by evaporating the solvent with a countercurrent of air at 80 – 100 °C in a 4- to 6-m spinning column. The fibers are then stretched while still plastic to increase their strength. Melt spinning of cellulose acetate or triacetate has no commercial importance due to the limited heat stability at the melting point.

A core-skin structure is formed in triacetate fibers. The acetyl groups are distributed very regularly in cellulose triacetate compared to secondary acetate; therefore, crystallization occurs when triacetate fibers are heated at 180 – 200 °C (heat setting) [107], [111], [112]. This heat treatment, which enhances the wash-and-wear properties of triacetate textiles, requires several minutes at 180 °C or several seconds at 220 °C. Heating for shorter periods is not effective and longer heating periods lead to deterioration of the mechanical properties of the textile. Heat-setting reduces water retention to 10 % and water absorption to 2.5 %.

2.3.4. Uses

By blending and twisting of cellulose acetate or triacetate fibers with nylon or polyester a combination of properties is achieved that make them suitable for different end uses in linings. In this way the weaker physical properties of acetate fibers can be compensated for while maintaining the positive characteristics, for instance, the high moisture absorption and the silk-like softness.

Due to the unique hydrophobic – hydrophilic properties, semipermeable membranes made from cellulose acetate fibers have a remarkable potential in desalination (reverse osmosis) of water.

Cellulose acetate hollow fibers are also suitable for gas separation and hemodialysis [113].

For cellulose acetate is non-toxic, biodegradable and the raw material is a renewable natural polymer, it is expected to find application for other uses in the future.

2.3.5. Economic Aspects

Secondary acetate and triacetate fibers for textiles and filter cigarette tow accout for 80 % of all cellulose ester production. The balance is used for plastics and film. Secondary acetate and triacetate textile fibers have a small share (about 1 %) of all textile fiber production.

In the late 1990s synthetic fiber production continued to expand (Table 17), whereas the acetate production was stable at about 850 000 t/a. The acetate fiber production decreased slightly compensated by a slight increase in filter tow production. The five largest manufactures of filter tow are Hoechst-Celanese and Eastman Chemicals in the United States, Rhodia Acetow

in Germany, Daicel in Japan, and Courtaulds in the United Kingdom.

2.4. Plastic Molding Compounds from Cellulose Esters

In the category "plastics made from natural materials," thermoplastics based on cellulose esters or cellulose mixed esters are still the most important [115].

As early as 1920, A. Eichengrün developed thermoplastic cellulose ester molding compounds as a spraying and molding powder. Cellulose acetate and mixed esters are used in injection molding and extrusion; mixed esters are also used for fluidized-bed dip coating and rotational molding.

The use of inorganic cellulose esters (see Section 1.2.7) is continually decreasing in the plastics sector because of their high flammability.

2.4.1. Physical Properties

Like cellulose acetate, cellulose mixed esters can be plasticized at elevated temperatures by using plasticizers. This results in a large number of grades with property combinations found in no other type of thermoplastic.

Thermoplastic cellulose ester molding compounds are generally characterized by good transparency, high mechanical strength, and toughness; one particularly noteworthy feature is that the material reacts to mechanical stresses by exhibiting cold flow, so that the otherwise problematic insert molding of metal parts presents no problems and there is no risk of stress cracking. Light-stable, transparent material is available in a wide range of transparent, translucent, and opaque color shades. High surface gloss coupled with antistatic properties (i.e., electrical charges disperse rapidly and no annoying dust patterns form) ensures that moldings retain their attractive appearance for years. High surface elasticity ensures a good "natural feel" and imparts a "repolishing" effect to the material: this means that scratches disappear as the object is being used. The relatively low modulus of elasticity gives excellent damping of vibrations, so that the acoustic behavior is not affected by annoying resonance or ambient noise.

The individual cellulose esters generally differ in their mechanical properties and in their compatibility with plasticizers. As a rule, cellulose mixed esters contain higher-boiling plasticizers in amounts ranging from 3 to 25 % whereas cellulose acetate contains 15 – 35 % plasticizers. Heat distortion temperature increases as the plasticizer content is reduced. Mixed esters absorb considerably less water than cellulose acetates, with the result that parts produced from mixed esters retain their dimensional stability even in humid climates. Finally, cellulose acetate butyrates and (with certain restrictions) cellulose acetate propionates can also be treated with UV inhibitors to ensure serviceability of the moldings even during years of outdoor exposure [116]. In principle, it is possible to reinforce thermoplastic cellulose ester molding compounds with glass fibers [117].

Figures 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22 show the physical properties as a function of the plasticizer content; the property levels may vary by as much as 15 – 20 % in either direction, depending on the type of plasticizer and the relative viscosity of the cellulose ester. In all of the diagrams and tables featured here, the abbreviations used are as follows:

CA = Cellulose acetate molding compound (acetic acid content > 55 %)
CP = Cellulose acetate propionate molding compound
CP∗ = Polymer-modified cellulose acetate propionate molding compound
CAB = Cellulose acetate butyrate molding compound
CAB∗ = Polymer-modified cellulose acetate butyrate molding compound

and cellulose acetate butyrate molding compounds.

2.4.2. Polymer-Modified Cellulose Mixed Esters

In 1977, cellulose acetate butyrate molding compounds modified with ethylene – vinyl acetate without monomolecular plasticizers were introduced for the first time [118]. They have since become firmly established, particularly in the extrusion sector (automotive decorative trim, etc.). As far as the property pattern was concerned, the decisive factor was the matching of the ethylene – vinyl acetate component to the cellulose acetate butyrate used.

A polymer modification of cellulose acetate propionate without monomolecular plasticizers has also been successfully carried out [119]. In this case, however, a modifier of complex structure, based on an ethylene – vinyl acetate graft polymer, is necessary [120].

The main advantages of these polymer-modified cellulose mixed ester molding compounds over the former plasticized systems are that the existing combination of characteristic properties is retained, while the values for heat distortion temperature, creep behavior, and stiffness are considerably improved.

Figure 28. Isochronous stress – strain curves of cellulose acetate, cellulose acetate propionate, and cellulose acetate butyrate for 1 h (determined in accordance with DIN 53444 or ISO/R 899)

Figure 29. Isochronous stress – strain curves of cellulose acetate, cellulose acetate propionate, and cellulose acetate butyrate for 1000 h (determined in accordance with DIN 53444 or ISO/R 899)

Another feature of these molding compounds is their freedom from plasticizer migration.

The polymer modifiers that are incorporated also delay the occurrence of crazing during long-term outdoor exposure, a fact which significantly increases the service life of, for example, external automotive decorative trim made from cellulose acetate butyrate molding compounds [118].

Some striking examples of the different properties of monomolecular-plasticized and polymer-modified cellulose acetate propionate and cellulose acetate butyrate are shown in Figures 27, 28, and 31.

Figure 30. Dynamic fatigue test in the range of pulsating tensile stresses (number of load cycles) of cellulose acetate$_{22}$, cellulose acetate propionate$_5$, and cellulose acetate butyrate$_{10}$ (determined in accordance with DIN 50100; stress amplitude $\pm\sigma_a$ ($N = 1$) means stress amplitude under initial loading)

Figure 31. Dynamic fatigue test in the range of alternating flexural stresses (number of load cycles) of cellulose acetate, cellulose acetate propionate, and cellulose acetate butyrate (determined in accordance with DIN 50100; stress amplitude $\pm\sigma_a$ ($N = 1$) means stress amplitude under initial loading)

Polymer modification has a similar effect on the tensile test, shear modulus, creep behavior, and hardness [119].

2.4.3. Chemical Properties

Thermoplastic cellulose ester molding compounds are resistant to white spirits, oil, and grease. Table 19 gives guide values for resistance to a range of substances, but thorough practical tests are recommended in each case.

Table 19. Typical values∗ for the chemical resistance of organic cellulose ester molding compounds

Solvent	Cellulose acetate (< 55 % acetic acid)	Cellulose acetate (> 55 % acetic acid)	Cellulose acetate propionate	Cellulose acetate butyrate
Water	+	+	+	+
Alcohols	− −	− −	− −	− −
Ethyl acetate	− −	0	0	0
Methylene chloride	− −	0	0	0
Acetone	0	0	0	0
Carbon tetrachloride	+	+	+ −	+ −
Trichloroethylene	+	+ −	− −	− −
Perchloroethylene	+	+	+ −	+ −
Benzene	+	+ −	− −	− −
Xylene	+	+	− −	− −
Petroleum spirit	+	+	+	+
Motor fuel mixture (high octane)	+	+	+ −	+ −
Mineral oil (paraffin)	+	+	+	+
Linseed oil	+	+	+	+
Turpentine oil	+	+	+ −	+ −
Lavender oil	+	+	− −	− −
Ether	+	+	+ −	+ −
Formalin	− −	− −	+ −	+ −
2-Chlorophenol	0	0	0	0
Sulfuric acid, conc.	−	−	−	−
Sulfuric acid, 10 %	+ −	+ −	+ −	+
Hydrochloric acid, conc.	−	−	−	−
Hydrochloric acid, 10 %	−	−	−	−
Nitric acid, conc.	−	−	−	−
Nitric acid, 10 %	−	−	−	−
Caustic potash solution, 50 %	−	−	−	−
Caustic potash solution, 10 %	−	−	+ −	+ −

∗ Key to symbols: + = resistant; + − = resistant, but swells; − = not resistant; − − = not resistant, swells; 0 = soluble.

2.4.4. Raw Materials

The following cellulose esters are used for the production of cellulose ester molding compounds:

Cellulose acetate propionate molding compounds,
55 – 62 % propionic acid content
3 – 8 % acetic acid content
Cellulose acetate butyrate molding compounds,
43 – 47 % butyric acid content
19 – 23 % acetic acid content
Cellulose acetate molding compounds,
51.6 – 56.3 % acetic acid content
51.5 – 53.5 % acetic acid content (for block acetate only)

Of the large number of plasticizers that are compatible with cellulose esters [6], the following have acquired industrial significance, either alone or in combination with one another:

For cellulose acetate propionates and cellulose acetate butyrates:
di-2-ethylhexyl phthalate, dibutyl adipate, di-2-ethylhexyl adipate, dibutyl azelate and dibutyl sebacate, dioctyl azelate, dioctyl sebacate, palmitates, stearates, etc.
For cellulose acetates:
dimethyl, diethyl, dibutyl, di-2-ethylhexyl, and di-2-methoxyethyl phthalate; triphenyl and trichloroethyl phosphate.

Ethylene – vinyl acetate copolymers have proven to be particularly suitable as polymer modifiers for cellulose acetate butyrate molding compounds, while graft polymers based on ethylene – vinyl acetate are preferred for cellulose acetate propionate molding compounds.

The *stabilizers* and *antioxidants* used for cellulose ester molding compounds include: alkali salts and alkaline-earth salts of sulfuric, acetic, and carbonic acid, tartaric acid, oxalic acid, citric acid, higher molecular mass epoxides, and phenolic antioxidants. In special cases these stabilizers and antioxidants can be complemented by others [121].

From the range of *ultraviolet absorbers* available, various benzophenones, benzotriazoles,

salicylates, and benzoates are recommended for organic cellulose ester molding compounds [122].

Processing auxiliaries for cellulose ester molding compounds include zinc stearate, butyl stearate, and paraffin oil.

Numerous combinations of *dyes* can be used for coloring cellulose ester molding compounds [123]. The following groups of dyes have proven successful in practice: alkaline, acid, and substantive dyes (provided they are sufficiently soluble in the solvent); Zapon, Sudan, and Ceres dyes (provided they are sufficiently resistant to sublimation); and organic and inorganic pigments.

2.4.5. Production

Like cellulose acetates, cellulose acetate propionates and cellulose acetate butyrates are also thoroughly mixed at room temperature with plasticizers, stabilizers, antioxidants, dyes, and sometimes ultraviolet absorbers and processing aids. Plastification and homogenization are carried out at higher temperatures (between 150 and 210 °C, depending on the type and the degree of plasticization) in single- or twin-screw kneaders or roll mills. Depending on the type of equipment used, this results in granules in the form of pellets (bulk density 500 – 620 g/L) or cubes (bulk density 400 – 470 g/L).

There are no wastewater or waste gas problems associated with the production of thermoplastic cellulose ester molding compounds. The inevitable plasticizer vapors that occur during processing should be removed by exhaust ventilation.

2.4.6. Trade Names

The most important trade names of thermoplastic cellulose mixed ester molding compounds are as follows:

Cellulose acetate propionates: Cellidor CP (Bayer AG, Leverkusen, Federal Republic of Germany), Tenite Propionate (Eastman Chemical Products, Inc., Kingsport, United States).

Cellulose acetate butyrates: Cellidor B (Bayer AG, Leverkusen, Federal Republic of Germany), Tenite Butyrate (Eastman Chemical Products, Inc., Kingsport, United States).

Cellulose acetate: Acety (Daicel, Osaka, Japan), Cellidor S (Bayer AG, Leverkusen, FRG), Dexel (Courtaulds Chem. and Plastics, GB), Saxetat (VEB Eilenburg, GDR), Setilithe (Tubize Plastics, Belgium), Tenite Acetate (Eastman Chemical Products, Inc., Kingsport, United States).

2.4.7. Quality Requirements and Quality Testing

As has already been stated, the mechanical properties of thermoplastic cellulose ester molding compounds are dependent on the chain-length of the molecules, on the plasticizer or polymer modifier, the combination of plasticizers, and the content of plasticizer or polymer modifier.

With respect to cellulose acetate, determination of the viscosity and the viscosity ratio in a dilute solution [124], determination of the insoluble constituents [125], viscosity loss during molding [126], light absorption before and after heating [127], and the determination of constituents which are extractable with ethyl ether [128] are all standardized. The methods described for cellulose acetate are similarly applicable to cellulose mixed esters.

The manufacturers also carry out numerous in-house tests during the course of their quality control programs. These include determination of mechanical data, testing of purity, checking thermal stability, colorimetry, determination of flow properties (melt index, Brabender, extrusiometer), etc.

In the Federal Republic of Germany, cellulose ester molding compounds (CA, CP, and CAB) are standardized in accordance with DIN 7742, Parts 1 and 2, and in the United States in accordance with ASTM D 706 (cellulose acetate), D 707 (cellulose acetate butyrate), and D 1562 (cellulose acetate propionate).

2.4.8. Storage and Transportation

The transportation of thermoplastic cellulose ester molding compounds is not governed by the GGVS/ADR, GGVE/RID, GGVSee/IMDG code or DGR/ICAO regulations for the transportation of hazardous goods. The storage of

thermoplastic cellulose ester molding compounds presents no problems. Even after 10 years in storage, no changes in composition have been detected. It is, however, recommended that thermoplastic cellulose ester molding compounds should be predried in accordance with the particular manufacturer's guidelines before processing.

2.4.9. Uses [129]

In the field of injection-molded eyeglass frames, cellulose acetate propionates have become increasingly important. This is due mainly to the fact that their dimensional stability is better than that of cellulose acetate, as a result of lower moisture absorption and greater stiffness and dimensional stability under heat [130].

Cellulose acetate propionate is also used for high-quality frames for sunglasses, protective goggles for industry, and sports goggles [130].

Cellulose acetate still dominates as sheet material for making ophthalmic frames. For this purpose, uni- or multicolored plates are either cast or made by extrusion.

Due to its high transparency, good impact resistance, and low level of light scattering, cellulose acetate propionate has become increasingly popular as a glazing for visors (for skiers, drivers, and workers in industry) and for sunglasses and sports goggles. These applications have been made possible by surface saponification of the plastic, which ensures permanent antifogging properties (the surface has very good wetting properties and excellent water absorption) [130].

Cellulose acetate propionates with special infrared/ultraviolet-absorbing characteristics have become more important for welding goggles and certain types of sunglasses [130].

Where greater demands are placed on impact resistance, cellulose mixed esters as well as cellulose acetate are used (e.g., for the production of tool handles, hammer heads, and covers for handles of pliers, wrenches, etc.). Particularly important factors in this field of application are toughness, transparency, lightfastness, the "natural feel," the repolishing effect, and the absence of stress cracking. No problems occur when metal parts are insertion molded (the blades can even be driven "cold" into the handles), which brings obvious economic advantages.

With their minimal plasticizer migration, cellulose mixed esters are preferred over cellulose acetate for the packaging of toiletries. Other reasons for their use in this sector include the brilliance and depth of color, as well as the ability to produce special color effects.

Resistance to stress cracking and good toughness properties make cellulose mixed esters an excellent material for brushes, particularly toothbrushes, for which new designs require close spacing of the drill holes and a high bristle density. Cellulose mixed esters also satisfy the requirement for high tuft pull-out strength.

Cellulose acetate butyrate sheet is used for illuminated advertising signs, machine hoods, lamp covers, and dome lights. High light transmission, practically unrestricted choice of colors, antistatic characteristics, easy accurate processing, ease of joining (by simply gluing), good printing and coating properties, the absence of stress cracking, and finally, excellent mechanical strength are the main factors influencing the choice of this material. Cellulose acetate propionate is used in place of cellulose acetate for transparent, large-size seat shells.

Transparent, thin-section, and large-area hoods, lids, and covers with excellent toughness and good weathering resistance are injection-molded from specially modified cellulose acetate propionate.

Decorative trim made of cellulose acetate butyrate combined with aluminum foil [131] has been firmly established in industry for years. An aluminum foil is coated with the cellulose mixed ester and shaped in the crosshead die of an extruder [132]. With its practically unlimited scope for metal and wood effects, its elasticity, resistance to detergents, and simple fixing, this combination of materials has been used with great success in the automotive industry [133] in particular, as well as in the electrical, audio, and domestic appliance sectors [134].

Further applications for cellulose esters include lamp covers, toilet seats, writing and drawing instruments, tap handles, casings for disposable hypodermic syringes, transparent mouthwash spray attachments, handles, high-quality toys, instrument panel covers (glazing), and knife handle grips.

Economic Facts. With an apparently guaranteed supply of raw materials and a tremendous scope for variation of cellulose ester molding compounds and of their property combinations, this class of plastics should maintain its market significance in special areas of application for years to come.

2.4.10. Toxicology and Occupational Health

Cellulose acetate and cellulose propionate molding compounds comply with Recommendation XXVI of the Federal Health Authorities of the Federal Republic of Germany [135].

There are also various cellulose ester molding compounds on the market which satisfy the requirements of the U.S. Food and Drug Administration for plastics [136].

1. Introduction

Cellulose ethers are nontoxic, usually water-soluble, white to yellowish powders or granules. There are some cellulose ethers that are not soluble in water, but their share of sales is insignificant as compared with the water-soluble substances. Cellulose ethers are produced by a polymer-analogous reaction of cellulose with low-molecular alkoxylating agents, which can support further functional groups.

The manufacture of cellulose ethers was first published in an article by W. Suida [1] in 1905 and the first patents [2] relating to their industrial production were issued as early as 1918. In the decade between 1920 and 1930 carboxymethyl cellulose was the first cellulose ether to gain economic significance, followed by methyl celluloses and hydroxyethyl cellulose some ten years later. These three product categories still dominate the market today.

During the time cellulose ethers have been used, continuous intensive research focusing on production processes and applications has been carried out by both industry and academia. Research was and is imperative to enable this group of substances to be utilized in ever new applications. Despite major progress in the areas of regioselective synthesis and analytics over recent years, the potential of these substances has by no means been fully exploited [3, 4].

Cellulose ethers can be sorted by their economic significance. The most important products in terms of sales are carboxymethylcelluloses (approx. 230 000 tons per annum), methyl- and hydroxyalkylmethylcelluloses (approx. 120 000 t/a), hydroxyethylcelluloses (approx. 60 000 t/a) and hydroxypropylcellulose (less than 10 000 t/a). The demand is served by a small number of manufacturers, which employ proprietory processes and have developed their own areas of expertise.

2. Properties

Cellulose ethers are nontoxic, usually water-soluble, white to yellowish powders or granules.

There are some cellulose ethers, that are not soluble in water, but their share of sales is insignificant as compared with the water-soluble substances.

The bulk density of cellulose ethers is between 300 and 600 g/L. They are lightfast and their storage life is claimed by the suppliers to be between 18 and 36 months. Cellulose ethers turn brown at elevated temperatures (around 200 °C) and show signs of decomposition above 250 °C. Their biodegradability can be influenced by the degree of substitution.

Cellulose ethers are capable of swelling or are colloidally soluble; they increase the viscosity of the solvent and develop a specific rheological profile. Depending on the substitution, cellulose ethers in solution are surface-active (surface tension: water 72 mN/m, carboxymethyl cellulose 70 mN/m, hydroxyethyl cellulose 63 mN/m, methyl cellulose 54 mN/m). The nonionic derivatives are film-forming substances, resulting in transparent films with a high elasticity. Solutions and films obtained from cellulose ethers are compatible with other hydrocolloids.

In many applications, however, where certain properties of an initially dry mixture such as dissolving and solvent binding behavior (water retention) are required, cellulose ethers are not used in ready-made solutions, but are blended with other solids,.

These three characteristics – dissolving behavior, the resultant solution structure, and the cellulose ether's capability of binding solvents – depend on molecular characteristics such as the type, number and distribution of the substituent and the molar mass distribution.

In technical specifications generally only the degree of purity, the viscosity in aqueous solution and in some cases the degree of substitution are stated.

2.1. Swelling and Dissolving Behavior

The different swelling and dissolving behavior of the various cellulose ethers originates from the interplay of the hydrogen bonds between free OH groups on the one hand and hydrophilic and hydrophobic substituent groups on the other. This interplay can be imagined as being the gradual introduction of hydrophobic substituents into native cellulose. Starting from a crystal structure based on hydrogen bridges, the partial imperfection of this structure caused by substituents results in free hydroxyl functions, hence first the substance becomes soluble in alkalies and subsequently in water. Further etherification with hydrophobic substituents results in solubility in organic solvents and ultimately thermoplasticity (intrinsic solubility).

Alongside the hydrophilic-hydrophobic interaction which culminates in "thermodynamic solubility", the particle-size distribution has a crucial impact on the obtainable state of solution. Particle size determines the kinetics of the dissolution process. If the particles are too large, they may not dissolve fast enough; they will swell and release some of their outer layer into the solution; due to the rising viscosity the mobility within the solution will decrease, leaving undissolved particle residues which will no longer dissolve in a reasonable time. Particles, that are too small, on the other hand, may cause formation of lumps during the dissolving process. Again this will ultimately result in undissolved particle residues preventing formation of a homogeneous solution.

To counteract these problems, most suppliers issue recommendations as to which particle size is best for a particular application. Some suppliers also offer specially treated products for enhanced dispersibility. These are mostly powder grades, whose initial dissolving rate is greatly reduced ("delayed or retarded solubility") to ensure that the substance is homogeneously distributed in the solvent before starting to dissolve. This delay can be achieved, for instance, by a reversible cross-linkage with glyoxal. The rate of dissolution is thus pH-dependent.

2.2. Solution State

The state of solution obtained, i.e., the sum of the interaction between the cellulose ether and the solvent and the intramolecular and intermolecular interaction of the cellulose ether molecules, determines the rheological profile of a solution or of an end product.

The standard rheological models of polymer chains dissolved in coil formation can be used to describe the characteristics of cellulose ether solutions, depending on the intrinsic viscosity

(also referred to as Staudinger index) and concentration. All known polymeric solution states from the diluted particle solution to the concentrated network solution [5] can thus be described. However, on account of their inclination to form aggregates, cellulose ethers often set scientists impossible tasks to solve.

The viscosity of a cellulose ether solution is generally stated as a characteristic feature. Measured in a 2 wt% aqueous solution, it is sometimes included in the product grade designation for orientation purposes. At first glance this seems to be useful, because many application-related properties are dependent on the same molecular parameters as viscosity. On closer, more discriminating examination, however, this turns out to be misleading, first because the dissolving and measuring methods differ from one supplier to another, which can result in a similar product having twice the viscosity, and second because – although giving a rough guide – the viscosity does not describe the solution structure and seldom the product's behavior in the final application system.

In the range relevant to the applications the viscosity of cellulose ether solutions rises disproportionately with increasing concentration and intrinsic viscosity:

$$\text{viscosity}_{\text{solution}} \propto \text{viscosity}_{\text{solvent}} \bullet (\text{concentration} \bullet \text{intrinsic viscosity})^{\frac{3.4}{a}}$$

($0.5 < a < 1.0$; a: exponent of the Mark-Houwink equation)

Most solutions show a pseudoplastic behavior, which is very important in practical terms.

Many cellulose ether solutions manifest time-dependent rheological functions, so the measurements depend on how the sample has been pretreated. The elasticity of the solutions also increases with rising concentration and intrinsic viscosity, but the exponents are different from those of the viscosity function; therefore the cellulose ether selected can modify the ratio of viscosity to elasticity within certain limits [6]. Some application systems exhibit a solid-like behavior at low shear stress and viscous flow only starts at stress levels above the so-called yield stress (plastic flow behavior).

The intrinsic viscosity describes the volume "filled" by the free molecule. The intrinsic viscosity is often used as a measure of the molar mass or chain length; the correlation is shown by the Mark-Houwink equation. When the intrinsic viscosity is gauged, not only the molar mass is determined but also the quality or performance of the solvent. Therefore effects attributable to pH, temperature and low-molecular salts, which have a substantial impact on the solution structure, are also part of the analysis. Many cellulose ethers can be salted out by "removing" the hydration shell of the molecules. With the ionic products, polyelectrolytic effects such as "repulsion" or "cross-linking" due to the charging of the macromolecules among themselves or with the charges of salts present in the solution also need to be observed.

The maximum possible thickening effect is predetermined by the used cellulose. The actual viscosity achieved by a cellulose ether depends on how well chain scissions can be prevented during the production process and on the type and quantity of substituents introduced into the cellulose molecule. Each substituent represents an increase in molar mass without an increase in the chain length. This reduces the thickening effect. The substituents are, of course, indispensable for solubility and other properties; however, derivatives which predominantly carry substituents with a low molar mass and where the degree of substitution is not too high are particularly effective thickeners. The substituent group with the lowest molar mass is the methyl group which simultaneously cancels out the intermolecular hydrogen bonds very effectively. As pure methyl cellulose manifests a specific temperature-dependent dissolving behavior, which restricts its universal use, mixed cellulose ethers with a low degree of substitution with hydroxyethyl or hydroxypropyl groups are generally used as high-viscosity thickeners, for instance in the construction sector.

The amount of cellulose ether used or its concentration in an aqueous solution has a similarly great effect as that of the chain length. When used as a thickener, the concentration range employed is usually in the range of a moderately concentrated network solution in which the polymer chains are not isolated but looped, forming a temporary physical suspension network.

The temperature dependence (below the flocculation point) of the flow behavior of aqueous cellulose ether solutions follows the principle

of temperature-time superposition. At a higher temperature all the molecules move faster. If a flow curve (shear stress as a function of the shear rate) is plotted at a reference temperature, the flow curve determined at a higher temperature follows the same shear stress path, except that it is merely shifted to higher shear rates. Accordingly, at the higher temperature the viscosity values are on a lower level.

Changes in flow behavior are thus predeterminable (as long as there is sufficient distance from the flocculation point). Therefore, when using the cellulose ether as a thickener in aqueous systems, the rheological behavior can be very reliably estimated above and below the reference temperature, if the flow activation energy is known. In the case of many cellulose ethers in aqueous solution the flow activation energy is in the proximity of 40 kJ/mol. Additional substances dissolved in the water may cause a shift in this value, but there is no fundamental change in the correlations.

2.3. Thermally Induced Coagulation

The solubility of cellulose ethers with hydrophobic substituents like methoxy groups decreases as the temperature rises, i.e., the performance of the solvent deteriorates. Cellulose ether dissolved in a cold solution can be made to coagulate by heating the solution. The process is reversible: when the solution cools down, the cellulose ether dissolves again. Depending on the selected type and degree of substitution, the flocculation point of industrial used products is varied between 30 and 100 °C.

This is an important characteristic for industrial production of cellulose ethers because in this way byproducts and salts can be washed out with hot water instead of with mixtures of water and alcohol.

To assess the flocculation point with mixed substituent groups, suitable flocculation diagrams have been published [7].

2.4. Degree of Substitution

The type of substituent and the degree of substitution determine most of the properties of a cellulose ether. With substituent groups where no secondary substitution is possible (methyl, carboxymethyl), the molar substitution (MS), i.e., the absolute number of substituents per anhydroglucose unit, is identical to the degree of substitution (DS), i.e., the number of substituents directly linked to the anhydroglucose unit. In the case of substituents containing hydroxyl groups (hydroxyethyl, hydroxypropyl), for example, further (secondary) reactions with the substituent can occur, i.e., there is no decrease in the number of reactive centers. With these products a distinction has to be made between MS and DS. Comparing MS and DS shows the proportion of side-chain substitution. On account of the simpler analytics involved, frequently only the MS is stated.

To examine the characteristic features more precisely, it is necessary to analyze the substituent distribution. Primary substitution (i.e., prior to any secondary reactions with the substituent) already involves three kinds of distribution:

- Substituent distribution within an anhydroglucose unit: depending on the reagent, the distribution can be between C-2, C-3, and C-6. This distribution can be analyzed by means of nuclear resonance spectroscopy or hydrolysis and subsequent chromatography [8].
- Substituent distribution along the backbone chain: in contrast to the random distribution normally found, a strictly uniform substituent sequence along the chain or a block structure formation are conceivable as theoretical borderline cases, which show up the different effects on solubility and therefore on the properties in general. To gain an impression of the distribution along the chain, various breakdown methods and subsequent liquid chromatography or derivatization and gas chromatography coupled with mass spectroscopy are used to obtain the proportions of non-, mono-, di- and trisubstituted anhydroglucose units. To assess the distribution of these units along the chain, the results of analysis of fragments of various lengths can be compared. Appropriate methods have so far only been developed for particular derivatives and only few research scientists have a good command of them [9, 10].
- Substituent distribution between the individual chains: the substituent density can also

vary between the individual chains of the cellulose ether, one known example being the nonsubstituted cellulose fibers in otherwise clear-soluble products. With ionic products the interchain distribution can be detected by polarographic analysis and an appropriate method for other derivatives is chromatography after specifically marking the free hydroxyl groups. The problem with both methods is that the molar mass distribution has to be known in order to carry out the assessment [11].

In the case of derivatives where a reaction with the substituent is possible, the potential number of different anhydroglucose units and their distribution increases randomly, and the structure becomes enormously complex. At the same time, however, the possibilities for adapting the hydrophilic-hydrophobic interaction to suit individual applications increase as well.

2.5. Molar Mass Distribution

Knowing the molar mass or the molar mass distribution makes it possible in theory to access various material functions. An absolute determination of these variables has so far only been achieved in isolated cases and with an enormous research input. Due to the "poor solubility" and the propensity of most derivatives toward association, producing time-stable molecularly disperse solutions is only rarely possible. Frequently it is a mixture of molecules, associates and aggregates that is analyzed, and the results are often impossible to interpret reliably.

It is precisely because of this complexity that so many attempts to make a breakthrough have been launched in the past, starting with "batch methods" such as static and dynamic light scattering in many different solvents, and "classifying" methods such as ultracentrifugation, size-exclusion chromatography and flow-field-flow fractionation, and also combined methods involving chromatography and various detection systems. All these approaches have in common that, although they give an interesting insight into the solution structure, the results often depend on how the samples have been prepared and how they are influenced by the measuring procedure itself. Taking the measuring conditions into account, some vital assertions can be made relating to existing systems. However, only in rare cases do the results stand up to comparison (between various methods) in respect of an "absolute" molar mass distribution.

3. Production

Cellulose consists of chains of anhydroglucose units (AGUs) linked together glycosidically (β-1-4-bonds) (→ Cellulose). Accordingly, each AGU still has three free hydroxyl groups which vary in their reactivity and which can be converted to ether groups in polymer-analogous reactions.

The free hydroxyl groups form intermolecular and intramolecular hydrogen bonds, so before the cellulose can be etherified it needs to be 'activated'. For this purpose the cellulose is chemically converted, usually with sodium hydroxide solution (caustic soda), in order to open up its natural structure and to obtain a sufficiently swollen material that is accessible to further reagents. The outcome is known as alkali cellulose or soda cellulose. The degree of swelling is controlled by the ratio of sodium hydroxide solution to cellulose and by the method of adding suspending agents or swelling agents. A minimum quantity of alkali (approx. 0.8 mol per mole of AGU) is required to swell the cellulose and for the reagents. During this activation process several properties of the end product are predetermined, because the degree of swelling and the uniformness of the activation influence the distribution of the substituents introduced in the second stage of cellulose ether production.

After the cellulose has been activated, the etherifying reagent is added. In principle, any etherification reaction known in the context of low-molecular alcohols could be applied, many of which have been studied [3]. Two basic types have become established in the industrial production of cellulose ethers – reactions where sodium hydroxide solution is consumed (e.g., Williamson ether synthesis) and reactions where sodium hydroxide only acts as a catalyst (e.g., alkoxylation). The supernatant caustic solution is neutralized after the reaction.

The kind of cellulose and its quality are crucial with regard to the ultimate properties of the cellulose ether. Therefore, many different types

of cellulose obtained from wood pulp or cotton linters are used. The type of cellulose used determines, among others, the maximum chain length, hence the viscosity yield of the final cellulose ether. The chain length is reduced on account of the chemical and thermal stresses imposed during the process. The incidence of chain scissions is inherent in the production process but can be selectively increased. Oxidative, acid and radiation-induced decomposition are some of the known degradation processes which, depending on the product category, are used at various points in the process to obtain a desired low viscosity.

Processes. The processes depend on the synthesis-related reaction stages which can take place in one set of equipment or in several sets arranged in sequence.

A distinction is made between reactions at ambient pressure and reactions carried out at up to 30 bar, depending on the different reagents and on the required weight percentage of cellulose or cellulose ether in the reaction medium (mass fraction). Heterogeneous syntheses are used for industrial-scale production, whereas homogeneous syntheses are so far only found in research. Heterogeneous systems are classified by mass fraction into suspension processes (mass fraction below 10 wt%) and slurry processes (mass fraction approx. 10 – 50 wt%). There is also the option of a gas-phase or vapor-phase process, that works without an inert liquid. The process technology and engineering is adapted to meet the requirements of the mass fraction involved.

The cellulose is usually supplied as rolls of cellulose webs or as cellulose sheets. In the early days of cellulose ether production, the cellulose was treated in an alkali bath (approx. 15 – 20 wt% caustic soda) with the disadvantage that the cellulose had not been ground and was therefore not fully accessible to the activating agent. Consequently, the activation process took 4 h and the ripening time 8 h or more [13]. During the ripening process the alkali cellulose was kept in intermediate tanks where the reaction was allowed to complete at a specific temperature. Prior to the ripening stage any excess activating agent was pressed out and the alkali cellulose was then shredded. Storing it in ripening tanks made handling more difficult and reduced its processability.

To make the cellulose more accessible to the chemicals involved, in modern processes the cellulose is generally ground or milled before the activating and reaction stages. The cellulose is then alkalized with highly concentrated (approx. 30 – 70 wt%) aqueous caustic soda solution. Alkalization usually takes place in mixers or stirred reaction vessels, depending on the mass fraction and the reaction system. The mass fraction can be selected to influence the water balance which affects side reactions or reagent yield and also the quality of the cellulose ethers. The way the chemical reaction is engineered during the alkalization stage also has a significant effect on the quality of the cellulose ethers (see above).

The reaction can be carried out either batchwise, semibatchwise (fed batch) or continuously, and the reaction temperatures vary from room temperature up to 110 °C, depending on the type of etherification. Here again, mixers and stirred vessels are the established equipment. There are some isolated patents describing continuous processes in different equipment setups [14 – 16]. The starting materials are fed as solids or liquids under pressure. In some older processes for the production of methyl or hydroxyalkylmethyl celluloses gaseous reagents are used.

The equipment assembled downstream of the reaction depends on the required degree of purity. In general a distinction is made between technical and nontechnical cellulose ethers which differ in their content of byproducts and neutralization products – predominantly salts. Depending on the washing agents and the type of wash (displacement or dilution-type wash) the equipment used for solid-liquid separation includes suction filters, belt filters, drum filters, centrifuges and decanters, operating either continuously or batchwise. The washing processes are carried out in aqueous or alcoholic media, depending on the product group.

If the product is still wet with solvent after the washing sequence, the inert dissolving or washing agents can be recovered by displacing them with water prior to the drying stage. Suitable equipment for this are, for example, continuous mixers. Auxiliary facilities are used for regenerating the reagents and washing media and for extracting byproducts.

At the end of the process line the products are converted in forming stages from their fibrous form into the required supply form, usually powder grades with a defined particle size distribution and containing small amounts of residual moisture (in most cases < 10 wt%). Various drying and comminuting equipment is used in a number of different combinations. This process step is also utilized for modifying the cellulose ethers so that they offer optimal properties for the individual fields of application. The particle size distribution ranges from granular grades with an average grain diameter of approx. 0.5 mm to very fine powders where the percentage of particles with a diameter of less than 63 µm is higher than 50 wt%.

4. Product Groups

4.1. Carboxymethyl Cellulose (CMC)

In terms of sales volume carboxymethyl celluloses are the largest product group. They are available in various levels of purity from completely "unpurified" to "highly purified" for food-grade applications. The CMC group also includes mixed ethers with hydroxyalkyl substituents, that have a predominantly ionic character. The structure of CMC is shown in Figure 1.

Figure 1. Structure of CMC

4.1.1. Applications / Market

The market can be divided into two segments: one for "purified" and another for "unpurified" CMC. However, the terms "purified" and "unpurified" are subject to regional and supplier-specific differences in definition. Products with an active content of 55 – 85 % are considered to be "unpurified"; 85 – 95 %: "semi-purified"; around 98 %: "purified"; and products with an active content greater than 99.5 % are classed as "highly purified" (high-purity grades).

Annual sales worldwide amount to approx. 230 000 t, of which purified CMC accounts for 130 000 t and unpurified CMC totals 100 000 t. It is difficult to accurately apportion figures to the two segments, not only because of varying definitions but also due to the fact that in some applications both purified and unpurified grades of CMC can be used, and many suppliers have both purified and unpurified products in their portfolios.

CMC can be produced with less technological input than the other cellulose ethers, which explains why a comparatively large number of manufacturers (more than 20) exists. The leading producer is CP Kelko with a market share of around 33 %. The largest regional market and the region with the largest production capacity is currently Europe, which still accounts for some 60 % of global capacity.

The initial application fields of CMC were detergents, where it acts as a soil carrier, and in deep-well drilling for oil and water, where it is used as a flotation aid in drilling mud. Unpurified grades were and in some cases still are used in these applications. Purified products are used in surface coatings and various other technical areas such as in the paper industry for coatings and pulp sizing to improve fiber retention, filler/pigment/dye yield as well as strength. CMC also improves the printability and smoothness of paper. Together with gelatin CMC is used as a coacervate to encapsulate ink in the production of noncarbon copy papers. Users of high-purity grades include the cosmetics and pharmaceutical industries, where CMC is used for instance as a fat-free ointment base or as a tablet disintegrant. In food and pet food production CMC's simplest function is to improve consistency and to provide a low-calorie replacement for starch and proteins, or to control more complex functions such as the freeze-thaw stability of deep-frozen products or the creaminess of ice cream.

4.1.2. Synthesis

CMC is produced in a Williamson ether synthesis from alkali cellulose with sodium chloroacetate or with chloroacetic acid itself, which reacts in-situ with caustic soda to form the salt. The process takes place in an aqueous or aqueous-alcoholic medium (slurry). The alcohols used are ethanol, isopropanol, *tert*-butanol and mixtures thereof.

$$\text{Cell}-\text{OH}\cdot\text{NaOH}+\text{ClCH}_2\text{COONa}\rightarrow$$
$$\text{Cell}-\text{O}-\text{CH}_2\text{COONa}+\text{NaCl}+\text{H}_2\text{O}$$

Alkalyzation is carried out at room temperature; the reaction takes place between 50 °C and the boiling point of the slurry medium under appropriate system pressure. The reaction is exothermic. With an activation energy of 87.9 kJ/mol it is highly temperature-dependent. The yield from this reaction in relation to chloroacetic acid is between 65 % and 80 %. Hydrolysis of chloroacetic acid occurs as a side reaction, forming glycolate. Commercial CMCs are produced with a degree of substitution between 0.2 and 1.5. Carboxymethylation takes place with a slight preference toward C2- followed by C6- and C3-substitution of the anhydroglucose unit [17].

4.1.3. Processes

In the early days of CMC production the cellulose was activated in alkaline steeping tanks [18]. After the excess caustic soda solution had been pressed out and the alkali cellulose had been shredded to fibers, the reaction was carried out with the addition of sodium chloroacetate in a kneader, where temperatures reached 30-35°C. The reaction was completed in a tumbling drum at 50 °C. The material was then washed with a mixture of methanol and water, filtered, ground and finally dried.

The first continuous process was used by Wyandotte Chem. Corp. (1947), but there was no washing stage, so it was only suitable for unpurified CMC [19]. Sodium hydroxide solution and monochloroacetic acid were added to the ground cellulose in a rotating drum. After a dwell time of 3 h the product was allowed to "ripen" for 10 h in drums.

In contemporary CMC production processes the ground cellulose is processed batchwise either as a suspension in the case of a low mass fraction of cellulose or, if the mass fraction is high, in mixers in the presence of "inert" media (see Fig. 2). Both processes use one or more short-chain alcohol(s) as a mass-transfer and heat-exchanging medium or as a suspending agent. For processes with a high mass fraction ethanol is usually employed a slurry medium, whereas isopropanol is used in suspension-type processes [20, 21]. By placing several sets of the same kind of equipment in parallel or in series it is possible to implement a quasi-continuous operation in the activation and reaction stages.

The starting materials and suspension or slurry media are either solid or liquid at normal room and reaction temperatures. Activation and reaction can therefore be carried out at ambient pressure.

Depending on the required product purity, the product is washed with alcohol-water mixtures, preferably with the same alcohol used in the reaction. Washing with water is not possible because of the water-solubility of the products. To meet product purity requirements, it is necessary to remove the alcohols from the product after the washing stage and prior to the grinding and drying processes.

Suspension agents and washing liquids are collected and reprocessed either by distillation and extraction or membrane processes.

4.1.4. Characterization

Carboxymethyl cellulose becomes water-swellable or alkali-soluble even at a low degree of substitution. The water-solubility of industrially produced CMC begins at a DS of approx. 0.6. The solubility increases up to a rather theoretical DS value of 3.0. Research work has shown that products with a lower degree of substitution (DS < 0.6) can manifest good solubility, the reason being different substituent distribution along the backbone [22].

Aqueous carboxymethyl cellulose solutions have very complex solution structures, because boundary conditions such as pH or salts simultaneously affect various characteristics. The solution state achieved depends, as with other cellulose ethers, on the nature of the dissolution pro-

Figure 2. Reaction mixer processes for purified CMC production

cess and the performance of the solvent. The parameter "solvent performance" covers all thermodynamic effects of protons, salts and other low-molecular substances on the interaction between the solvent and the macromolecule.

In addition CMC is a weak carboxylic acid. The proton concentration in the solution not only affects the solvent's performance but simultaneously alters the number of free carboxylate groups. CMC's equivalence point is at a pH of 8.25; its pK_a value is between 4 and 5. In its acid form CMC is insoluble in water. Depending on the degree of substitution CMC can be precipitated from the solution at low pH values. Deprotonation increases with rising pH values and the character of the polyelectrolyte becomes apparent: The repulsion among the individual substituents becomes more distinct and the salt sensitivity increases. When CMC comes into contact with selected divalent or trivalent salts, this leads to complexing and in some cases to interlinking and precipitation of the CMC. With divalent salts these effects depend largely on the ratio of substituent to salt [23].

The many different possibilities of microscopic interaction are also reflected in the macroscopic properties of CMC. From a rheological point of view CMC solutions are inclined to form superstructures. Viscosities of 2 wt% solutions ranging from 3 mPa·s to 100 000 mPa·s are available on the market. Most of the products exhibit pseudoplasticity, some of them a thixotropic behavior. Depending on the selected degree of substitution and the product group, the solutions are either smooth-flowing or highly gelatinous.

Commercial grades are not only categorized according to their purity, their morphology and their mean viscosity, but also according to their degree of substitution. Water-soluble CMC commodities are available with a DS of around 0.7, 0.9 and 1.2. These three product groups do not only differ in their DS, but also in their solution structure, hence their rheological behavior.

4.2. Methyl and Hydroxyalkyl Methyl Celluloses

Pure methyl cellulose (MC) and hydroxyalkyl methyl celluloses (HAMC) are collectively known as methyl cellulose. Pure methylcellulose only accounts for a minor share of the market. The mixed ethers hydroxyethyl methyl cellulose (HEMC, see Fig. 3) and hydroxypropyl methyl cellulose (HPMC) have established themselves in particular for technical applications.

Figure 3. Structure of HEMC

4.2.1. Applications / Market

The market for methyl cellulose and hydroxyalkyl methyl celluloses was in the range of 120 000 t in 2003, the market leader being Dow Chemical Company, with Shin-Etsu Chemical and Wolff Cellulosics having slightly lower market shares. High-purity grades are marketed for applications in the food, pharmaceutical and cosmetics sectors and purified products are used in building materials and industrial applications. The building material segment is by far the largest field of application.

The applications and therefore also the types of product used in the building materials sector vary from region to region due to different construction methods and traditions (→ Dry Mortars). In the USA joint compounds account for the largest segment; in Europe the main applications of MC and HAMC are plasters, renders, and tile adhesives. Efficient modern application methods would not be possible without the use of methyl celluloses. Properties such as water retention, open time, wet adhesion, initial thickening and setting behavior are regulated using only low additive contents of between 0.01 and 2 wt% (in relation to the building material system). Accordingly, the cellulose ether has to meet high quality requirements.

In the life-science sectors only nonhydroxyalkylated methyl cellulose (modified vegetable gum) and hydroxypropyl methyl cellulose (carbohydrate gum) are used. In the pharmaceutical industry methyl celluloses are employed as tablet base and in coatings of controlled-release drugs. In the food and cosmetics industries it is the thickening and emulsifying properties that are exploited to give the products the desired consistency and texture. The most noteworthy industrial application is the use of highly methylated hydroxypropyl methyl cellulose as a protective colloid in the polymerization of vinyl chloride.

4.2.2. Synthesis

The synthesis of hydroxyalkyl methyl cellulose is a combination of both principles of synthesis in industrial cellulose ether production: methylation is along the lines of Williamson ether synthesis where a stoichiometric amount of NaOH solution is consumed, whereas alkylation only requires catalytic amounts of alkaline solution.

Pure MC is produced from alkali cellulose by a reaction with gaseous or liquid methyl chloride. In side reactions the methyl chloride is hydrolyzed to form methanol, and subsequently the methanol is etherified by methyl chloride, forming dimethyl ether. The reactions take place between 70 and 120 °C. Methylation is an exothermic reaction, the activation energy being 80 kJ/mol.

$$\mathrm{Cell{-}OH{\cdot}NaOH + ClCH_3 \rightarrow Cell{-}O{-}CH_3 + NaCl + H_2O}$$

The grades produced have a degree of substitution of 1.7 and 2.3. In case of pure methylation the substituent is found to prefer C2-, followed by C6- and C3-positions of the anhydroglucose unit [25, 26].

In the course of hydroxyalkyl methyl cellulose production alkoxylation of the cellulose takes place prior to or parallel to its methylation. As both the cellulose and the alkoxy groups formed can be methylated and alkoxylated, the outcome is a potentially indefinite number of

different products, allowing the range of properties to be tailored to the requirements of specific applications.

4.2.3. Processes

The development of processes to produce methyl cellulose and hydroxyalkyl methyl celluloses began with methods at ambient pressure, i.e. gas circulation processes, where the cellulose is activated (for example by a steeping process), shredded and subsequently brought into contact with the reagents in a mixer. Nonreacted gaseous feed materials and byproducts are continuously extracted, the byproducts are condensed out and the gas flow is returned to the reactor. The product is then washed, filtered, compressed, ground and dried.

The slurry process (see Fig. 4), operated at pressures of up to 30 bar, is the process in most widespread use today for producing HAMC batchwise or semibatchwise in a mixer. Processes patented in the 1950s suggest the use of pressure-resistant reactors without any additional inert slurry media [27]. More recent patents propose adding inert slurry media, mostly ethers [28]. The slurry medium acts as a heat-transfer medium, which evaporates and is condensed in a dome-shaped condenser.

The reagents are added to the ground cellulose in any sequence, depending on the targeted product characteristics. The slurry medium has to be added prior to etherification on account of the heat generated during the exothermic reactions. Once the reaction has been completed, low-boiling slurry media are extracted by reducing the pressure and are collected for reuse. Byproducts are discharged. High-boiling slurry media are separated during the washing stage and subsequently reprocessed.

Suspension-type processes are mentioned in several patents. Their advantages are their simple process engineering, whereas disadvantages can be seen in the more complex preparation of the suspension agent.

The flocculation point of MC and HAMC allows the products to be washed with water above this flocculation point. To do so, the contents of the reactor are led into a stirred tank filled with hot water or they are suspended in the reaction mixer; the salts formed during the reaction are dissolved and any nonreacted activation reagents are neutralized with acid. The suspension is then separated in a solid-liquid separating unit. Further washing stages may be required, depending on the product specifications, in order to comply reliably with restrictions in content of byproducts.

Again depending on the type of product, the HAMC is then conditioned for the grinding and drying stage. Drying and grinding can be carried out in succession or in combined milling and drying units. The required fineness of grind, i.e., the particle size, which in some cases is less than 63 μm in more than 50 wt% of the product, can often only be achieved in screening and sifting stages, after which the coarse-grained material is recycled.

4.2.4. Characterization

With a degree of substitution of around 1, methyl celluloses exhibit good water solubility at room temperature. The higher the degree of substitution, the better the solubility in water. However, it decreases again with further methylation and changes to solubility in organic solvents at a DS of approx. 2.6, because the material becomes increasingly hydrophobic.

Available on the market are pure methyl celluloses with a degree of substitution between 1.7 and 2.3, hydroxyethyl methyl celluloses with methylation levels between 1.3 and 2.0 and ethoxylation levels between 0.1 and 0.4, and hydroxypropyl methyl celluloses with degrees of methylation between 1.3 and 2.1 and of propoxylation between 0.1 and 1.0. The limits of substitution are more or less predetermined by the products' flocculation point, because washing with water is less expensive than with alcohol.

The flocculation point, i.e., the gelation and subsequent coagulation as the temperature rises, is a characteristic found only in nonionic cellulose ethers. By varying the methyl and/or alkyl content of hydroxyalkyl methyl celluloses, it is possible to modify the macromolecule's affinity to its water shell and therefore the flocculation point: with increasing methyl substitution the number of hydrophilic groups is reduced, and the flocculation point drops. Accessibility to the hydrophilic groups increases in proportion to the

Figure 4. Modern HAMC production process

rise in hydroxyethylation, and the flocculation point shifts to higher temperatures. (The introduction of hydroxypropyl substituents results in opposite characteristics where, depending on the degree of substitution, the flocculation point either rises or drops.) Especially for applications where there is a high ambient temperature, e.g. on building sites in the summer, a methyl cellulose (MHEC or MHPC) with a sufficiently high flocculation point should be used to eliminate any undesired changes in characteristics.

The rheological properties of methyl celluloses and hydroxyalkyl methyl celluloses vary within a broad range, exhibiting some very different features, because there is a wide viscosity range in the grade spectrum available and because the products can have very differing chemical structures.

Products with a particularly low viscosity, such as HPMC for tablet coatings with a typical viscosity of between 3 and 6 mPa·s at a concentration of 2 wt% in water, still show a purely Newtonian (ideal) flow behavior in aqueous solutions with a HPMC concentration of 10 – 20 wt% at room temperature, and the viscosity of these solutions can be as high as 10 000 mPa·s. The Newtonian behavior is crucial for spraying highly concentrated solutions and for good leveling and film formation.

HEMC or HPMC grades with a higher viscosity for use as thickeners, however, exhibit a non-Newtonian flow behavior even with at low concentrations. In building materials applications, such as tile adhesives, the high static shear viscosity guarantees standing strength and resistance to demixing as well as high water retention, while the non-Newtonian properties ensure rapid and easy workability. The thickening characteristics of nonionic cellulose ethers are scarcely affected by the presence of dissolved (even polyvalent) salts or by changes in the pH value, so they are also ideal for use in cement-based building materials in which, after water is added, highly alkaline conditions prevail.

The most effective way to achieve good thickening at a low shear rate is to use small input quantities of high-viscosity grades. In these systems the viscosity soon drops considerably as the shear rate increases. A high thickening effect at high or at least at medium shear rates is desirable for improved workability in certain high-quality building material systems, and it can only be obtained with higher levels of methyl cellulose, which also provide additional benefits, such as

long open times and improved adhesion in the case of tile adhesives.

4.3. Hydroxyethyl Cellulose (HEC) [29]

Hydroxyethyl celluloses are the third largest product group in the marketplace. They are nonionic and soluble in both cold and hot water. Their manufacture was first described in 1920 in a patent granted to Farbenfabriken Bayer. The structure of HEC is shown in Figure 5.

Figure 5. Structure of HEC

4.3.1. Applications / Market

The hydroxyethyl cellulose market is served mainly by Hercules Incorporated/Aqualon and Dow Chemical Company. Annual sales are around 60 000 t, most of which are used in the construction industry, and specifically in surface coatings. Hydroxyethyl cellulose is also found in cosmetic applications where it competes against HPMC derivatives. Other applications are in drilling fluids and as a protective colloid in emulsion polymerization.

In the paint industry HEC is the cellulose ether product group with the largest market share. Although products based on HEMC, HPMC or CMC have smaller shares, they are firmly established in these applications for technical and cost-related reasons. Beside pure HEC this product group also includes mixed cellulose ethers similar to HEC: ethyl hydroxyethyl cellulose (EHEC) and hydrophobically modified (hm) variants of HEC. The additional hydrophobic properties are imparted to hm-HEC by minor secondary substitution, for instance with long-chain alkyl residues (C_{12} through C_{24}) [30]. The hydrophobically modified grades are, like purely synthetic associative thickeners, capable of providing additional effects by interacting with particle surfaces, in particular those of the binder in latex paints, and by forming micelles and mixed micelles with other surfactants contained in the paint. These options are exploited especially in high-grade paint formulations in order to reduce spattering when applying the paint with a roller, and to obtain improved brush resistance and leveling.

4.3.2. Synthesis

Hydroxyethyl cellulose is formed by reaction of cellulose with ethylene oxide. This ethoxylation only requires catalytic quantities of alkaline solution.

$$\text{Cell}-\text{OH}+\text{OH}^- \rightarrow \text{Cell}-\text{O}^- + \text{H}_2\text{O}$$
$$\text{Cell}-\text{O}^- + \text{CH}_2\text{CH}_2\text{O} \rightarrow \text{Cell}-\text{O}-\text{CH}_2\text{CH}_2-\text{O}^-$$
$$\text{Cell}-\text{O}-\text{CH}_2\text{CH}_2-\text{O}^- + \text{H}_2\text{O} \rightarrow \text{Cell}-\text{O}-\text{CH}_2\text{CH}_2-\text{OH}+\text{OH}^-$$

Just as the cellulose alcoholate reacts with the ethylene oxide, also the hydroxyl ions present can react with the ethylene oxide or with the glycolates formed in the process. Large amounts of alkali reduce the yield of the main reaction, but to produce HEC a minimum quantity of caustic soda solution is essential to break down the cellulose.

Ethoxylation takes place in the presence of an "inert" solvent (isopropanol, *tert*-butanol, 1,2-dimethoxyethane or acetone); it starts at a very low temperature ($\approx 30\,^{\circ}\text{C}$) and is highly exothermic. HECs are produced with a molar substitution of 1.5 and 3.5, these degrees being controlled via the quantity of ethylene oxide added. The yield is between 40 and 75 % in relation to ethylene oxide. The reaction of ethylene oxide takes place in the following order of preference (from high to low): alkoxy groups, then C6 positions, then (followed by some distance) C2 and C3 positions [31]. The relationship of the reaction rates can be influenced by varying the alkali concentration, e.g., by partial neutralization [32]. After the reaction has taken place, the alkali quantity added needs to be neutralized.

Figure 6. Process for the production of HEC/HPC with stirred tanks

4.3.3. Processes

For the production of HEC, suspension processes above ambient pressure have become the established methods [33]. Stirred pressure vessels are used for the reaction (see Fig. 6).

The ground cellulose is suspended in the suspending medium and mixed with the alkalizing agent. After alkalization, liquid ethylene oxide is added to the suspension and allowed to react for about 2 h.

Salts and byproducts have to be washed out of the products. As with other cellulose ethers, this involves appropriate equipment for washing and solid-liquid separation either in series or in a combined unit. As this cellulose ether does not have a flocculation point, mixtures of water and an organic solvent are used, followed by drying and grinding.

Parallel to this, the suspension medium and any extracting agents have to be regenerated and recycled. Distillation is the method usually selected for this.

4.3.4. Characterization

Hydroxyethyl celluloses are available on the market with viscosities between 10 mPa·s and 100 000 mPa·s and molar substitutions of 1.5 and 3.0 (up to 4.5 in the case of hydrophobically modified grades). They are water-soluble and have no thermal flocculation point. Hydroxyethyl celluloses are also more difficult to salt out than methylated derivatives and are not displaced from water even by larger amounts of organic solvent. The degree of substitution varies in the region of 1 in industrially produced grades, i.e., higher hydroxyethylation leads chiefly to secondary, tertiary, and quaternary substitution of the hydroxyalkyl substituent (formation of ethylene oxide side chains).

The rheological behavior of HECs is comparable with that of carboxymethyl celluloses. By introducing a small number of hydrophobic side chains, grades can be obtained, whose rheological profile in solution is highly modified,

particularly when mixed with surfactants. The hydrophobic residues form part of the surfactant micelles and this increases the viscosity, especially at elevated shear rates.

4.4. Hydroxypropyl Cellulose (HPC)

In relation to the quantities of cellulose ethers used worldwide, hydroxypropyl celluloses are the smallest product group. Their properties range from simple swellability, through solubility in cold water to enhanced thermoplasticity, which enables them to be processed in melt extruders. Hydroxypropyl cellulose was first launched on the market in the USA at the end of the 1960s. The structure of hydroxypropyl cellulose is shown in Figure 7.

Figure 7. Structure of HPC

4.4.1. Applications/Market

The annual global market for hydroxypropyl cellulose is far below 10 000 t. The main fields of application are in the pharmaceutical and cosmetics industries [34]. High-purity grades are available for food and pharmaceutical applications, and purified grades are supplied to the cosmetics industry and for technical applications.

Hydroxypropyl cellulose is supplied by Hercules Incorporated/Aqualon, by Shin-Etsu Chemical and by Nippon Soda.

4.4.2. Synthesis

The synthesis of hydroxypropyl cellulose does not differ from that of hydroxyethyl cellulose. Prior to the reaction with propylene oxide, the cellulose is activated with caustic soda solution. The reaction has a somewhat higher activation energy and requires a higher reaction temperature than that with ethylene oxide. The byproducts are propylene glycol and polypropylene glycols which, like the salts from the neutralization stage, need to be removed in one or several washing stage(s).

4.4.3. Processes

The production processes for HPC are largely the same as for HEC. The reaction is generally carried out in a slurry. The slurry media described in relevant literature are hexane, toluene, tetrahydrofuran and dioxane, and also the common alcohols. Apart from the slurry process, the gas-phase method — which produces high-quality grades due to the high degree of substitution — is also applied. Since highly substituted HPC has a thermal flocculation point, however, washing can be carried out using hot water, which is not possible with HEC [35].

4.4.4. Characterization

Highly substituted hydroxypropyl cellulose is readily soluble in cold water and also soluble in polar organic solvents. The HPCs available on the market have a high molar substitution (3.0 – 4.5) and mean viscosities between 10 and 30 000 mPa·s. HPC solutions are generally smooth-flowing and exhibit scarcely any tendency toward thixotropic behavior. Gelation and coagulation begins at relatively low temperatures (40 – 50 °C). Hydroxypropyl cellulose is surface-active and tends to foam. Highly concentrated HPC solutions can develop liquid-crystalline phases. With a sufficiently high degree of substitution hydroxypropyl cellulose is thermoplastic and can be processed at approx. 150 °C. The extruded moulded parts are water soluble yet, due to their low propensity to absorb water, they are not sticky even when the humidity is high.

HPC with a low molar substitution of between 0.2 and 0.4, on the other hand, swells in water, but is not water-soluble. These grades are used as binders or disintegrants in the manufacture of tablets.

5. Uses

Cellulose ethers are used in a wide variety of fields ranging from oil drilling to industrial applications such as polymerization, from surface coatings and construction materials to the health care sector, cosmetics, food and pharmaceuticals. Not all types of cellulose ethers are equally suitable in all fields of application. Table 1 provides an overview of the great variety of applications and the appropriate types of cellulose ether. A listing of this kind can only be incomplete, but indicates the versatility and above all the adaptability of the products to the various fields in which they are to perform.

In many cases the amount of cellulose ether required is only between 0.02 and 2 %. This small level is, however, crucial for properties such as water-binding capacity, film formation and thickening as well as for controlling other rheological properties. Many modern products and processing techniques would not be possible without the use of cellulose ethers.

Each field of application requires specific solutions which in many cases involve modifying the cellulose ether product. This means that, once a suitable product category has been selected, all the parameters relating to the appropriate type of substitution and viscosity range have to be fine-tuned. Besides their chemical structure, characteristics such as product purity and forming, i.e., the physical state in which the products are made available, play a substantial part. Fine-tuning requires a great deal of experience in respect of the properties of these products as well as with regard to the systems and methods of application. Most suppliers provide this expertise and offer additional technical service.

6. Economic Aspects

In 2003 the sales volume of the cellulose ether market worldwide was approximately \$ 2×10^9. The largest market is Europe, followed by the USA and Japan. Annual consumption is ca. 420 000 t.

Sorted in the order of their economic significance (by sales volume), carboxymethylcelluloses rank first with approx. 230 000 t/a, while methyl- and hydroxyalkylmethylcelluloses are second with approx. 120 000 t/a, followed by hydroxyethylcelluloses on third place with approx. 60 000 t/a and last by hydroxypropylcellulose with less than 10 000 t/a.

Taking all market segments together, the cellulose ether market has grown continuously in recent years. However, there has been and still is a noticeable shift among the individual markets. As opposed to vigorous growth in the threshold countries and moderate growth in Europe and the USA, the Japanese market is dwindling.

The market is served overall by a small number of suppliers of cellulose derivatives. Most of the manufacturers produce a variety of different products for several market segments. The carboxymethyl cellulose market is spearheaded by CP Kelko, a company with a market share of 33 %. The remaining market is shared by 10 to 15 small to medium-size suppliers. The methyl and hydroxyalkyl methyl cellulose market is served by a few major producers [Dow Chemical Company, Wolff Cellulosics, and Shin-Etsu Chemical (incl. SE Tylose, the former cellulose ether division of Clariant AG)] with a market share totaling 80 %. Hydroxyethyl cellulose is supplied more or less exclusively by Hercules and Dow Chemical Company, whereas HPC is mostly supplied by Hercules and Shin-Etsu Chemical.

7. Toxicology and Occupational Health

Toxicology. Cellulose ethers are generally nontoxic. High-purity grades of most commercial products are approved as food additives and for use in cosmetic compositions.

Handling. Fine powders of cellulose ethers form explosive dusts in air as do natural polysaccharides or sawdust. Dry nonionic ethers undergo electrostatic charging similar to that of other organic polymers. When cellulose ethers are stored and handled, the general precautions concerning powdered organic polymers must be observed. The flammability is similar to that of cellulose. Spilling of solutions forms very slippery films that are difficult to remove.

Ecology. The biodegradation of cellulose ethers by cellulase-producing microorganisms also occurs in wastewater and therefore prevents the accumulation of cellulose ethers. Glucose, glucose ethers, and ether oligomers result from

Table 1. Major fields of application in which the individual product groups are used

Carboxymethyl cellulose	Methyl cellulose, hydroxyalkyl methyl cellulose	Hydroxyethyl cellulose	Hydroxypropyl cellulose
Paper	tile adhesives	latex paints	adhesives
Detergents	plasters/renders	adhesives	ceramics
Drilling for oil and gas	pharma/cosmetics	building materials	cosmetics
Pharma	joint compounds	cosmetics	encapsulation
Cosmetics	wallpaper paste	drilling for oil & gas	food
Textile industry	polymerization	agriculture	household goods
Food	food	paper	printing inks
Coatings	latex paints	synthetic resins	polymerization
Encapsulation	cement extrusion	textile industry	films

enzymatic hydrolysis; they are further degraded to carbon dioxide and water in slow bioreactions. Biostable or toxic metabolites are not known.

Cellulose ethers have no fish toxicity and are poor nutrients for most microorganisms. Nevertheless, wastewater bacteria may adapt to enhanced cellulose ether degradation after some exposure.

The suppliers provide Safety Data Sheets containing detailed data with regard to handling and the toxicological properties of the respective products.

1. Cement

Cement is a hydraulic binder. It is a finely ground, nonmetallic, inorganic material. When mixed with water it forms a paste that sets and hardens by hydration. After hardening, it retains its soundness, strength, and stability, even under water. The hydraulic hardening is primarily due to the formation of calcium silicate hydrates. Accordingly, cements consist of components which react within a short period of time with the mixing water to form such calcium silicate hydrates in due quantity to guarantee strength and durability. Besides calcium silicates, smaller amounts of other components, for example, calcium aluminates, take part in setting and hardening reactions. Calcium aluminate cements harden hydraulically by forming mainly calcium aluminate hydrates.

1.1. History

The name cement in the sense of building materials originates from the Romans, who called a concrete-like brickwork, made from stones and a burnt lime binder, *opus caementitium*. Later, hydraulic binders which were obtained from a mixture of additives such as ground ceramic bricks, volcanic tuff, and burnt lime were given the names cementum, cimentum, caement, and cement. The notation cement, known from metallurgical processes, is not linked with building materials.

The importance of clay for the hardening properties of hydraulic lime that is burnt from a natural mixture of limestone and clay was discovered by John Smeaton (1724 – 1792). This hydraulic lime was used to produce a seawater-resistant mortar for the Edystone lighthouse near Plymouth. The later cement chemist W. Michaelis called this discovery the basis of modern knowledge on hydraulic mortars. In a similar way in 1796 James Parker burnt a hydraulic lime from natural London marl and called it Roman cement.

Louis-Joseph Vicat (1786 – 1861) in France and Johann Friedrich John (1782 – 1847) independently discovered that artificial mixtures of natural limestone and 25 – 30 % clay were most suitable for the production of hydraulic lime. Even the binder produced in 1824 by Joseph Aspdin by burning an artificial mixture of limestone and clay corresponded formally and according to modern definitions to Roman lime in its composition and properties because it had not been burnt to sintering. He called this binder Portland cement, since the artificial stones made from Portland cement were similar in color to Portland stone, an oolitic limestone that was quarried on the channel coast of the Portland peninsula in Dorsetshire. William Aspdin (1815 – 1864), the son of Joseph Aspdin, started the production of Portland cement in 1843 in his newly established plant in Rotherhithe, near London. His cement proved to be far superior to Roman cement, as was demonstrated in the construction of the Houses of Parliament in London. The reason for this improvement was a higher burning temperature, which led to partial sintering of the raw mix. William Aspdin is therefore regarded as the first producer of real Portland cement.

The importance of the sintering process was pointed out for the first time on a more scientific basis by Isaac Charles Johnson (1811 – 1911) in 1844. The first German Portland cement, based on the Aspdin patents,

was produced in Buxdehude near Hamburg in 1850. The foundations for the production of Portland cement in Germany on an industrial scale were laid by HERMANN BLEIBTREU (1824 – 1881), who built two cement plants, in Züllchow near Szczecin (1855) and in Oberkassel near Bonn (1858). The production of Portland cement in France started in 1850 based on the finding that the sintered residue obtained when burnt lime was hydrated resulted in a slow-setting binder after grinding.

In the United States, DAVID SAYLOR first produced sintered cement clinker in 1870. He homogenized the raw material by grinding and then formed bricks from the resulting powder which were burnt.

WILHELM MICHAELIS (1840 – 1911) played an important part in further developments. His book *The Hydraulic Mortar*, published in 1868, described for the first time details of the optimal composition of the raw material mixture and the first valuable information on the highest possible content of calcium oxide in the raw material mixture, that is, the amount which is able to bind SiO_2, Al_2O_3, and Fe_2O_3 at sintering temperatures (hydraulic modulus). Further knowledge on reactions during burning and cooling of cement clinker resulted among others from the studies of S. B. and W. B. NEWBERRY [12], E. WETZEL [13], E. SPOHN [14], F. M. LEA and T. W. PARKER [15], and H. KÜHL [16].

In the early stages, only the simple, discontinuously operating shaft kiln was available, but later the annular brick kiln was also employed to burn cement clinker. The term *cement clinker* originates from this time, because the material to be burnt in the annular kiln was formed into bricks, which were placed and burnt like ceramic bricks. The first rotary cement clinker kilns were operated in the United States in 1895 and in Germany in 1896. Later, the first grate preheater kiln was introduced in Germany by Polysius in 1929. The first cyclone or suspension preheater kiln of industrial scale was built in 1953 by KHD, also in Germany, based on a Danish patent from 1932.

The latent hydraulic properties of granulated, that is, rapidly cooled and largely glassy, blast-furnace slag were discovered by EMIL LANGEN in 1862, who found out that a mixture of ground granulated blast-furnace slag and burnt lime can attain considerable strength. In 1882 GODHARD PRÜSSING (1828 – 1903) was the first to add ground granulated blast-furnace slag to Portland cement. Cement with a lower slag content was designated ″iron Portland cement″ in Germany in 1901, and the cement with a higher content of slag has been called ″blast-furnace slag cement″ since 1907. In 1908, H. KÜHL discovered the sulfate activation of granulated blast-furnace slag, which was the basis of the production of ″supersulfated cement″. The first cement characterized by a higher early strength was produced in an Austrian cement plant in Lorüns (Vorarlberg) in 1912. This was a very finely ground Portland cement from clinker, obtained by burning a lime-rich mixture of raw materials at a higher temperature.

The first Portland cement with a high sulfate resistance was the ″Erzzement″ patented by Krupp-Grusonwerk in Magdeburg in 1901 and produced in the cement plant in Hemmoor near Hamburg. It contained a smaller amount of aluminum oxide and a large amount of iron oxide, and this resulted in an alumina modulus of only 0.3. The properties of this cement are similar to those of the so-called *Ferrari cement*, a Portland cement with an alumina modulus of 0.64, which was first produced in Italy in 1919. The importance of a high slag content for the sulfate resistance of blast-furnace cements was established between 1920 and 1930. White Portland cement was produced in small amounts in the years after 1880 in the Portland cement plant near Heidelberg, Germany. Later, other cement plants also started the production of this kind of cement.

The development of *oil-well cement* started about 1930, when deep wells became necessary for the recovery of crude oil. These types of cement, which set and harden very gradually, even at high temperatures and pressures, are required to line the oil wells. The first description of *expanding cement* appeared in 1920 [17]. The expanding cements produced today are based on the work of V. V. MIKHAILOV and A. KLEIN [18]. The Portland Cement Association of the United States developed *regulated-set cement* [19]. A similar cement is the *jet cement* produced in Japan [20]. *Calcium aluminate cement* was first produced in France during World War I, based on a patent awarded to the French chemist J. BIED in 1908. He discovered that crystallized melts with the composition of monocalcium aluminate can

harden hydraulically and attain especially high early strength.

The first cement standards were introduced in Germany in 1878. In France, the use of cement for the construction of government buildings was permitted in 1885. The cement standards in the United States and Great Britain were established in 1904. The European Standard for Common Cements will be introduced in 2001/2002.

1.2. Cement Constituents

The production of cement includes extraction and preparation of the raw materials, burning of the raw materials mixture to give cement clinker, preparation of the different main components of the cement, and grinding of the cement components together with calcium sulfates to regulate setting. These continuous processes demand the monitoring of large material flows with respect to amount and required composition. This procedure is necessary to compensate variations of the raw materials composition or deviations caused by the process of clinker burning and cement grinding. Quality management systems according to DIN-ISO 9000 and DIN-ISO 14 000 support the effort to achieve a high level of product quality and uniformity, low energy consumption, and minimized emissions.

1.2.1. Portland Cement Clinker

Portland cement clinker consists mainly of tricalcium silicate, dicalcium silicate, tricalcium aluminate, and calcium aluminoferrite. It is made from a mixture of raw materials which normally contains limestone, clay, sand, iron ore, and other components in definite proportions. When this mixture is heated to the sintering temperature range, new compounds form, the clinker phases. Table 1 shows their proportions.

The terms alite and belite were introduced by A. E. Törnebohm, who examined clinker microscopically in 1897 [21]. He used the first letters of the alphabet to designate the main components because he did not know their composition. These names are still used to distinguish between pure silicates and silicate phases in clinker, which always incorporate small amounts of aluminum, iron, magnesium, alkali metals, and trace elements.

Tricalcium silicate (C_3S) (see Fig. 1) is the compound with the highest CaO content in the binary system $CaO-SiO_2$. C_3S decisively determines most of the properties of cement. It hardens quickly and attains a very high strength when it is finely ground and mixed with water to give a paste. It is formed by the solid-state reaction between calcium oxide and silica and can be produced from pure limestone and quartz. The starting materials must be very finely ground and burnt at extremely high temperatures. The reaction, however, proceeds more rapidly in the presence of a melt consisting of calcium, aluminum, and iron(III) oxides at about 1450 °C. For this reason, raw materials used in the production of Portland cement clinker contain predominantly calcium oxide and silica and additionally the necessary amounts of aluminum and iron(III) oxide to form a melt proportion of about 20 – 25 %.

Figure 1. Scanning electron micrograph (SEM) of idiomorphic alite crystals embedded in an undifferentiated matrix of Portland cement clinker

Pure tricalcium silicate melts incongruently at 2070 °C, releasing calcium oxide [22]. Tricalcium silicate is metastable below 1250 °C and decomposes to calcium oxide and dicalcium silicate. However, decomposition occurs only at very slow cooling rates and/or when Fe^{2+} instead of Fe^{3+} is present in the lattice [23]. Therefore, cement clinker that contains iron oxide should be burnt and cooled under oxidizing conditions. In the metastable temperature region below 1250 °C, six polymorphic modifications of tricalcium silicate have been identified [24].

Table 1. Phase composition of Portland cement clinker [11]

Constituent	Formula (abbreviation)	Content, wt % Range	Average
Tricalcium silicate	$3\,CaO \cdot SiO_2$ (C_3S)	46 – 79	61
Dicalcium silicate	$2\,CaO \cdot SiO_2$ (C_2S)	5 – 30	15
Calcium aluminoferrite	$2\,CaO \cdot (Al_2O_3, Fe_2O_3)$ [$C_2(A, F)$]	4 – 16	8
Tricalcium aluminate	$3\,CaO \cdot Al_2O_3$ (C_3A)	6 – 18	12
Free calcium oxide	CaO (C)	0.1 – 4	
Free magnesium oxide	MgO (M)	0.7 – 1.5	1.5

These are stabilized by solid solutions of such ions as Mg^{2+}, Zn^{2+}, Al^{3+}, and Fe^{3+}.

Dicalcium silicate occurs when cement clinker is not completely saturated with calcium oxide. Pure dicalcium silicate melts congruently at 2130 °C [22]. In lime-rich raw mixes, C_2S forms already at temperatures below 1000 °C by solid-state reaction. During the sintering process in the presence of a melt above 1250 °C, C_2S incorporates additional Ca^{2+}, resulting in the formation of C_3S. It crystallizes in four polymorphic modifications which are known under the designations α, α', β, and γ [24]. The β modification is metastable at all temperatures. It is converted to the less dense γ modification at below 500 °C. This conversion is the reason why a cement clinker rich in C_2S may disintegrate at low cooling rates. In industrial clinkers, however, burnt above 1200 °C, disintegration generally does not take place because the different high temperature modifications [24] of C_2S are stabilized by incorporation of, e.g., Al^{3+}, Mg^{2+}, P^{3+}, Na^{+}, K^{+} etc. The type of modification present in industrial clinkers additionally depends on the cooling rate. Commonly, C_2S exists in its β modification besides the α and α' modifications.

The high-temperature modifications of C_2S have hydraulic properties, in contrast to γ-C_2S. In cement, however, the hydration reaction of C_2S is slowed down significantly as compared to C_3S.

Calcium aluminoferrite [C_2(A,F)] contains most of the iron and part of the aluminum present in cement clinker. It is a phase in the limited solid solution series $2\,CaO \cdot (Al_2O_3, Fe_2O_3)$, with $2\,CaO \cdot Fe_2O_3$ (dicalcium ferrite) and $2\,CaO \cdot (0.69\,Al_2O_3, 0.31\,Fe_2O_3)$ as its limits. In common cement clinker, the composition of calcium aluminoferrite roughly corresponds to the formula $4\,CaO \cdot Al_2O_3 \cdot Fe_2O_3$. It can incorporate up to 2 wt % of magnesium oxide in its crystal lattice. This causes a change in color from brown to gray, the color of common Portland cement [25]. In clinker which is burnt under reducing conditions and which contains 0.2 – 0.3 % Fe^{2+} as a result, the remaining C_2(A, F) phase shows a brown color. Possibly, Fe^{2+} is bound in the lattice instead of Mg^{2+} [167]. Calcium aluminoferrite contributes little to the hydraulic hardening process. The hydraulic reactivity decreases with an increasing Fe_2O_3 content of C_2(A, F).

Tricalcium aluminate (C_3A) is the compound with the highest CaO content among the aluminate phases. C_3A contains the aluminum oxide that is not combined in calcium aluminoferrite. It melts incongruently, releasing calcium oxide. Pure C_3A crystallizes in cubic form. The lattice can incorporate different ions in solid solution, e.g., Fe^{3+}, Mg^{2+}, Si^{4+}, or K^{+} and Na^{+}. Due to the incorporation of alkali metals, the symmetry of crystallization changes from cubic to orthorhombic and monoclinic, and this results in a higher hydraulic reactivity as compared to cubic C_3A. Consequently, the technical properties of Portland cement clinker are changed (Section 1.6). Altogether, C_3A reacts rapidly with water, but its hydraulic properties are not very pronounced. However, together with silicates, it improves the initial strength of cement.

Free Lime (CaO) and Periclase (MgO). Minor components of cement clinker are free calcium oxide (free lime) and free magnesium oxide (Periclase). They react with water to form calcium hydroxide and magnesium hydroxide, which occupy more space than the original oxides. Therefore, free calcium oxide and free

magnesium oxide may cause expansion when they are present in larger amounts as coarsly crystalline components. In this case the reaction with water proceeds very slowly and still continues when the paste has already started to harden. Hence, all cement standards contain appropriate specifications to limit CaO and MgO contents so that damaging expansion does not occur and mortar and concrete keep their soundness.

Alkali metal compounds, such as alkali metal sulfates and alkali-metal-containing calcium aluminate, are also minor components of cement clinker which originate mainly from raw materials and fuel ashes. Clinker contains up to 2.0 wt % alkali metal oxides ($Na_2O + K_2O$) and up to 2.0 wt % sulfate (SO_4^{2-}). Molten alkali metal sulfate forms at sintering temperatures. It does not mix with the aluminoferrite melt in the clinker. Solid solutions of alkali metal sulfate crystallize during cooling with a composition that depends on the K_2O/Na_2O ratio. Components such as $2\,CaSO_4 \cdot K_2SO_4$ can also be formed. The molar ratio of alkali metals and sulfate in the clinker is designated as the degree of sulfatization. If an excess of alkali metal is present, alkali-containing calcium aluminate forms with a composition and crystalline structure similar to that of tricalcium aluminate [26]. The total amount of alkali metals and the nature of their binding in the clinker can significantly affect the setting and hardening of cement.

Other compounds which may occur in common Portland cement clinker generally do not have a significant influence on cement properties. Special cements may contain, e.g., calcium aluminates of different composition which determine the properties of the product in a characteristic way (see Section 1.3.3) and [164].

1.2.2. Granulated Blast-Furnace Slag (S)

Processing. Blast-furnace slag is obtained from nonferrous components of iron ore, coke ash, limestone, and other additives during the smelting of iron ore in a blast furnace. It is removed from the furnace separately or together with molten pig iron at temperatures of approx. 1350 – 1550 °C. It solidifies at about 1250 °C. Glassy blast-furnace slag is produced by rapidly cooling the molten slag with water and/or compressed air to get a finely dispersed material (granulation). The glass content, which is decisive for the hydraulic properties, must be kept as high as possible. Normally, the glass content is higher than 90 %. Standards require a glass content of at least two thirds of the mass [197]. Figure 2 shows the typical morphology of glassy grains.

Figure 2. Particles of rapidly cooled glassy blast furnace slag (SEM)

The moist granulated slag is stored for a limited time in large drained stockpiles to lower the moisture content and to homogenize different furnace charges. The granulated slag retains at least 7 – 20 % residual moisture and is dried in different kinds of drying equipment before grinding. In some cases it is dried while grinding cement by using the heat produced during grinding and/or hot gas. Altogether, the grinding of cements containing blast-furnace slag requires more energy than the grinding of Portland cement [165] to achieve a cement of a similar high efficiency as Portland cement.

Properties. In contrast to slowly cooled crystalline slag, glassy blast-furnace slag is a latent hydraulic material. It must be activated if it is to harden hydraulically in a commercially acceptable period of time. The activator in the case of Portland slag cement and blast-furnace cement is Portland cement clinker (clinker activation). In the case of supersulfated cement, it is anhydrite or gypsum (sulfate activation).

The hydraulic properties of glassy blast-furnace slag depend on the microscopically determined glass content and on its chemical composition [33]. Table 2 gives the chemical composition of blast-furnace slags used in Europe in

Table 2. Concentrations of main and minor chemical components in granulated blast-furnace slag, natural pozzolana, siliceous fly ash, and burnt oil shale [167]

Component	Granulated blast-furnace slag	Natural pozzolana	Siliceous fly ash (Germany)	Burnt oil shale
SiO_2	30 – 39	45 – 89	35 – 53	12 – 51
Al_2O_3	9 – 18	3 – 20	21 – 30	5 – 16
TiO_2	0.3 – 1.4		0.7 – 1.5	
P_2O_5	0.1 – 0.4		0.1 – 0.8	
Fe_2O_3	0.1 – 1.0 ∗∗	1 – 10	6 – 12	6 – 7
Mn_2O_3	0.2 – 3.0 ∗∗		0.1 – 0.4	
CaO	33 – 48	2 – 9	0.5 – 10	18 – 60
MgO	2 – 13	1 – 5	2 – 5	1 – 4
Na_2O	0.2 – 1.2	1 – 7	0.4 – 2.0	1 – 2
K_2O	0.4 – 1.3	1 – 11	1.0 – 5.0	1 – 2
SO_3	0.0 – 0.2	0.0 – 0.8	0.3 – 1.5	5 – 10
S^{2-}	0.5 – 1.8			

∗ The components are usually given as simple oxides. ∗∗ Calculated from FeO and MnO.

the production of cement [167]. In other countries the chemical composition may differ to a certain extent.

In general, the hydraulic reactivity of glassy blast-furnace slag is proportional to the amounts of calcium oxide and magnesium oxide. Whereas CaO increases the reactivity, MgO diminishes the hydraulic properties because of the formation of crystalline spinel ($MgO \cdot Al_2O_3$). A higher content of aluminum oxide especially increases the initial strength. The sulfide content promotes glass formation because the larger sulfide ions are incorporated into the glass structure rather than the smaller oxide ions.

Simple formulas, based on chemical composition, are used to evaluate the hydraulic properties of glassy slag. The European cement standard, for example, requires the ratio of $(CaO + MgO)/SiO_2$ to exceed 1.0. However, these formulas can only be applied to slag of the same origin. Moreover, the activating effect of the clinker and the curing conditions must be considered. Therefore, strength achieved by mortar test specimens made from slag-containing cements, considering the fineness, the particle size distribution, the proportion of the components, and the SO_3 content [167] is at present the only reliable means of evaluating the hydraulic properties of glassy blast-furnace slag. Additionally, the strength of mixtures of Portland cement with granulated blast-furnace slag is evaluated by comparison with mixtures containing an inert material of the same fineness, e.g., finely ground quartz [34], [35].

1.2.3. Pozzolanic Materials (P, Q)

Pozzolanas are naturally occurring siliceous or silico-aluminous fine-grained materials which at normal temperatures can only harden in the presence of water and calcium hydroxide. Major components of pozzolana are more or less reactive silica and various aluminosilicates. The proportion of reactive CaO is negligible. Products of the pozzolanic reaction are calcium silicate hydrates as strength-giving constituents. Additionally, calcium aluminate hydrates, obtained from the reaction of calcium hydroxide solution with reactive aluminum oxide, can influence the hydraulic hardening and the product properties. According to the European standard specifications [197], the reactive silica content must not be less than 25 %.

These properties are primarily exhibited by volcanic tuff which originates from volcanic ash deposits. The natural pozzolana (P) is named after the tuff deposit in Pozzuoli, near Naples, Italy, which has been used since ancient times. Even today, the volcanic tuff found in Campagna and Latium is of considerable importance to the Italian cement industry. The Rheinish trass found in the Neuwied basin near Koblenz, Germany, is also volcanic tuff. The Suevit or Bavarian trass occuring in the Nördlinger Ries was originally sedimentary rock, transformed by the impact of a meteorite.

Sedimentary rocks containing larger amounts of reactive silica also belong to the group of natural pozzolanic materials. They only need to be dried before they can be used as main constituent

in the production of cement. Rocks with a high content of free silica of organic origin, such as the diatomites found in northern Germany and Denmark and French gaize, also belong to this category.

Natural calcined pozzolanas (Q) are of volcanic or of sedimentary origin (e.g., clay and shale). They are heated to 400 – 800 °C to increase their reactivity. This applies, e.g., to phonolite, an alkali-rich volcanic rock. The zeolite present in phonolite is converted to reactive silica when it is heated. Table 2 lists the chemical compositions of natural pozzolanas.

The reactivity of pozzolanic materials can be determined, as in the case of blast-furnace slag, by their contribution to the strength development of mortar test specimens [34–36]. The European cement standard requires a special test for pozzolanic cement, a procedure which has long been part of the Italian cement standard. This test shows that the pozzolanic portion of cement has the ability to bind a certain minimum amount of the calcium hydroxide released during hydration of the clinker portion. The lower the pozzolanic reactivity, the higher the content of pozzolanas must be to meet the standard requirements. However, the proportion in the cement is limited to meet the minimum requirements on strength and durability.

Rocks, generally also including tuff, are quarried by blasting and are then crushed to the size of gravel. Sedimentary rocks are directly removed from the quarry front. The materials are dried and, if necessary, heated in a kiln. They are then ground with Portland cement clinker and calcium sulfate to give pozzolanic cement.

1.2.4. Fly Ash (V, W)

Fly ash is a fine-grained residue from the combustion of pulverized coal. It is precipitated in the electrical or mechanical dust-collecting equipment of power plants. Fly ash may be of siliceous or calcareous nature. The former has only pozzolanic properties. The latter may additionally have hydraulic properties. The unburnt residue is normally limited to 5 wt % as loss on ignition. The fineness is in the range of 2100 – 6200 cm^2/g (Blaine). Siliceous fly ash (V) consists mainly of fine-grained, partly glassy particles, which are usually spherical but can also have an irregular shape and a porous structure. Fly ashes from wet-bottom boilers contain about 85 wt % and those from dry-bottom boilers less than 61 – 76 wt % of glass, with available Al_2O_3-contents of 14 – 25 wt %. Crystalline components are mullite, quartz, and magnetite [167], as well as small amounts of alkali metal chlorides and sulfates. Table 2 lists the chemical composition of siliceous fly ashes, and Figure 3 gives an example of its morphology. The properties of fly ash, especially the amount of unburnt or partially burnt coal, of quartz, and other crystalline components are mainly determined by the origin of the coal, the ash content and also by the firing and combustion conditions.

Figure 3. Morphology of siliceous fly ash (SEM)

Calcareous fly ash (W) having pozzolanic and/or hydraulic properties consists essentially of reactive CaO, SiO_2, and Al_2O_3. As defined by EN 197-1, the portion of CaO must not be less than 10 wt %, in contrast to siliceous fly ash. The portion of hydraulic compounds may increase with increasing CaO content. Therefore, calcareous fly ashes with more than 15 wt % of reactive CaO have to exhibit a compressive strength development in mortar (EN 196-1) of at least 10 MPa after 28 d. Calcareous fly ashes with CaO contents between 8 and 40 wt % which result from burning lignite from the Rhine area of Germany contain large amounts of free lime and anhydrite ($CaSO_4$) and therefore do not easily meet the requirements regarding soundness.

1.2.5. Burnt Oil Shale (T)

Burnt shale, specifically burnt oil shale, is another main constituent for the manufacture of

cement. Its use is dependent on the composition. In Germany, such material is found in the area northwest of the Swabian Mountains and is used for this purpose. This oil shale is a lime-containing bituminous shale with ca. 11 wt % of organic substances, 41 wt % calcium carbonate, 27 wt % clay minerals, and 12 wt % quartz [38]. It is burnt at 800 °C in a fluidized-bed furnace. The energy released when oil shale is burnt is utilized to generate electricity, and the ash is ground with cement clinker to give Portland/burnt (oil) shale CEM II/A/B-T cement and other binders. Oil shale can also be used as a raw material component in the clinker burning process.

The chemical composition of burnt oil shale is characterized by the figures listed in Table 2. Burnt oil shale itself is able to harden hydraulically according to the requirements of EN 197-1. This is due to its content of dicalcium silicate and various calcium aluminates. Mainly the high content of reactive silica additionally shows pronounced pozzolanic properties.

1.2.6. Limestone (LL, L)

Limestone, under practical conditions, acts as a filler in cement. A filler is defined as a cement component which does not participate, or only slightly participates, in the hardening reactions of the hydraulically active components. However, as a result of its physical properties, especially its particle size distribution, it improves the properties of fresh and hardened cement paste, mortar, or concrete. This effect proves to be the more significant, the steeper the particle size distribution of the Portland cement component. It is based on the filling out of hollow spaces between the cement particles. As a result, the particle size distribution of the filler-containing cement in the RRSB grid becomes broader. The water demand of the paste, mortar, and concrete is reduced, and the workability improved [168], [169]. This leads to a denser structure, and the filler can increase the strength to a limited extent without taking part in the hardening reactions [39]. For compensation of the diluting effect of amounts higher than, for example, 10 wt % of limestone filler, the Portland cement clinker portion in the cement should be ground to a higher fineness. The amount of filler should not exceed 20 wt %. The filler must not impair other properties; for example, it should not decrease the frost resistance of concrete made from this kind of cement. Therefore, the limestone employed has to meet requirements on $CaCO_3$ and TOC contents and on methylene blue adsorption [197].

1.2.7. Silica Fume (D)

Silica fume is a byproduct of the production of silicon and ferrosilicon alloys. It consists of very fine and mainly spherical particles with a BET specific surface area of at least 15 m^2/g but normally higher than 20 m^2/g. Consequently, silica fume has a low bulk density. This is the reason why this material is compacted or pelletized before transport or handled as slurry when used as a concrete additive.

The content of SiO_2 must not be less than 85 wt % [197]. Other components may be Al_2O_3, Fe_2O_3, MgO, and CaO, depending on the kind of production process. The SiO_2, especially that from ferroalloy production, has an amorphous structure. Therefore, silica fume commonly has a marked pozzolanic reactivity. It reacts with calcium hydroxide to form calcium silicate hydrates. Besides its use as a main constituent in cement, silica fume is also used as an additive in high-strength concrete. The extreme fineness of silica fume increases the water demand of paste, mortar, and concrete. Therefore, the employment of water-reducing admixtures is necessary.

1.2.8. Other Constituents

Minor additional constituents are defined as specially selected, inorganic, natural and mineral materials, derived from the clinker production process [197]. After appropriate preparation and on account of their particle size distribution they improve the physical properties of cement, such as water retention and workability. Their addition in limited to 5 wt %.

Additives for the purpose of improving the manufacture or the properties of cement must not exceed a total quantity of 1 wt % [197].

Calcium sulfate is added to cement and interground to control setting. Sulfates also act as activators for strength development. For reasons

of soundness the total sulfate content (SO_3) of cements must be less than 3.5 (4.0) wt %. Added calcium sulfate can be natural gypsum ($CaSO_4 \cdot 2\,H_2O$), natural anhydrite ($CaSO_4$), or a mixture thereof. Gypsum is partly dehydrated at mill temperatures above 80 °C to form hemihydrate ($CaSO_4 \cdot 0.5\,H_2O$). Calcium sulfate is also available as a byproduct of some industrial processes. Gypsum from flue gas desulfurization of power plants has proved suitable. For the reaction of water-soluble sulfates with calcium aluminate hydrates to adjust the setting time of cement and the workability (optimization), see Section 1.6.

1.3. Types of Cement

Different economic and industrial developments, sources of raw materials, and climatic conditions have led to different developments in building methods and construction materials and, therefore, to different types of cement. Hence, there have always been substantial differences in the national standards for composition, strength development, and other properties. With the elaboration of a European cement standard an attempt was made to adopt all cements described as traditional by the respective national standardization bodies, which have been produced and used for decades and which have proven durability performance in practice. Due to the large number of different cements involved it was considered necessary to separate "common cements" from "cements with special properties". Although the European standard for common cements has not yet been formally introduced by the national standardization bodies, the basic principles of the standard have already been adopted in most of the existing national standards.

1.3.1. Standardized Common Cements

The European cement standard EN 197-1/2 [197] exclusively contains cements which can be used for general purposes. Cements with special properties such as low-heat cements, sulfate-resistant cements, and calcium aluminate cements will be specified separately. On a national basis separate standards for different cement types as well as one standard for all cement types do exist. The standard EN 197-1 distinguishes between five main types of common cement:

- CEM I: Portland cement
- CEM II: Portland composite cement
- CEM III: Blast-furnace cement
- CEM IV: Pozzolanic cement
- CEM V: Composite cement

These five main types are subdivided into 27 different products (types of common cement; Table 3).

CEM I is a Portland cement with a clinker content of at least 95 wt %. The main type CEM II includes all composite cements which contain 6 – 20 (A) and 21 – 35 wt % (B) of one or more main constituents (see Section 1.2) besides clinker. The content of silica fume is limited to 10 wt %. CEM III designates all granulated cements containing blast-furnace slags with a slag content of 36 – 65 (A), 66 – 80 (B), and 81 – 95 wt % (C). CEM IV are Pozzolana cements with pozzolan (D, P, Q, V, W) contents of 11 – 35 (A) and 36 – 55 wt % (B). CEM V are composite cements containing granulated blast-furnace slag (S) and pozzolana (P, Q, V) in a total portion of 36 – 40 (A) and 62 – 80 wt % (B) as main constituents besides clinker.

1.3.2. Standardized Special Cements

European standards for cements with special properties are not yet available. Therefore, national regulations are still applicable.

Sulfate-resistant cements (SRC) are to be used for concrete structures which are exposed to the attack of soluble sulfates in ground waters, surface waters, and soils. Portland cements (CEM I) with a low C_3A content of less than 3 wt % and blast-furnace cements with at least 65 wt % of granulated blast-furnace slag are well tried in Europe and other parts of the world and meet the requirements for chemical resistance. Additionally, on a national basis, several cements of the main types CEM I – V with common composition are standardized as sulfate-resistant cements, seawater-resistant cements, or as medium sulfate-resistant cements. The suitability of these cements, however, depends on

regional environmental conditions. Without further experience based on long-term investigations, general adoption into a European regulation does not seem to be practicable.

Table 3. Cement types and composition specified in EN 197-1

Main cement types	Ordinary cement types	
CEM I	Portland cement	CEM I[a]
CEM II	Portland slag cement	CEM II/A-S[a] CEM II/B-S[a]
	Portland silica fume cement	CEM II/A-D
	Portland pozzolanic cement	CEM II/A-P[a] CEM II/B-P[a] CEM II/A-Q CEM II/B-Q
	Portland fly ash cement	CEM II/A-V[a] CEM II/B-V CEM II/A-W CEM II/B-W
	Portland shale cement	CEM II/A-T[a] CEM II/B-T[a]
	Portland limestone cement	CEM II/A-L CEM II/A-LL[a], [b] CEM II/B-L CEM II/B-LL
	Portland composite cement	CEM II/A-M CEM II/B-M[c]
CEM III	Blast-furnace cement	CEM III/A[a] CEM III/B[a] CEM III/C
CEM IV	Pozzolanic cement	CEM IV/A CEM IV/B
CEM V	Composite cement	CEM V/A CEM V/B

[a] Cement types standardized in DIN 1164-1. [b] Corresponds to the CEM II/A-L Portland limestone cement currently standardized in Germany with a limestone TOC content of ≤ 0.20 wt % by weight [c] Only CEM II/B-SV Portland fly ash slag cement is currently standardized in DIN 1164-1.

Low-heat cements (LH), used in massive concrete structures, are characterized by limitated exothermic heat release during hydration. The heat of hydration leads to an increase of concrete temperature which may cause mechanical tension and formation of cracks.

The heat of hydration is mainly estimated according to two methods, standardized on a European basis. The heat of hydration is measured by solution calorimetry [170] after hardening of the paste under strictly isothermal conditions. The heat development of a mortar is measured continuously in a calorimeter under semiadiabatic conditions [171]. Low-heat cements are required to release a heat of hydration of not more than 270 J/g of cement [166]. Further subdivisions of the LH standard are under discussion. Characteristic for the LH cements is a decreased early strength development. LH CEM cements will be grouped in the five main cement types CEM I to CEM V.

Low-alkali cements (NA) are used in the production of concrete which contains aggregates with alkali-reactive constituents and which is used under moist atmospheric conditions. Low-alkali cements are defined worldwide as cements with a maximum total alkali content of 0.60 wt %, calculated as Na_2O (equivalent), and in Germany as cements containing granulated blast-furnace slag (Table 4).

Table 4. Specification of low-alkali cements (DIN 1164, 1999)

Cement type	Slag content, wt %)	Na_2O (equiv), wt %
All		≤ 0.60
CEM II/B-S	21 – 35	≤ 0.70
CEM III/A	36 – 49	≤ 0.95
CEM III/A	50 – 65	≤ 1.10
CEM III/B	66 – 80	≤ 2.00

Calcium aluminate cement with an Al_2O_3 content between 36 and 55 wt % is a hydraulic binder which sets and hardens by formation of aluminate hydrates. The main constituent is monocalcium aluminate ($CaO \cdot Al_2O_3$, CA). Other mineral phases as minor constituents include calcium aluminate ferrite $2\,CaO \cdot (Al_2O_3,\ Fe_2O_3)$ ($C_2(A,F)$), dicalcium silicate $2\,CaO \cdot SiO_2$ (C_2S), and Gehlenite $2CaO \cdot Al_2O_3 \cdot SiO_2$ (C_2AS). The hydraulic properties are predominantly based on the hydration of CA. High early strength development of more than 20 N/mm^2 after 6 h and more than 40 N/mm^2 after 24 h together with normal setting behavior ($>$ 60 min) and a high chemical resistance of dense mortars and concretes are the main characteristics of this cement. Increasing Al_2O_3 contents result in a rising refractory resistance. The kind of hydration products and the structure formed are dependent on the temperature during hydration. Hydration below

25 °C leads to metastable hexahydrates CAH_{10}, C_2AH_8, and Gibbsite (AH_3). In course of time CAH_{10} and C_2AH_8 transform into stable cubic hydrogarnet C_3AH_6 with an increase of porosity. Therefore, future specifications [172] will require a hydration temperature of more than 40 °C to achieve the direct formation of stable hydrogarnet and to avoid the porosity increase by conversion.

1.3.3. Other Cements

There are many different cement types with individual properties which are often used for special purposes only. In most cases they are not standardized but may be introduced into the market on the basis of national approval. Some examples are given below.

Approved cements for the production of *shotcrete* are mainly fine-ground Portland cements with or without addition of small amounts of calcium sulfate. The initial setting time after water addition is required to be less than one minute and may be regulated by calcium sulfate additions. Water-repellent additives are used to avoid prehydration and strength loss of the cement caused by moist aggregates. The use of soluble alkali metal silicates (water glass) as accelerator is questionable with regard to a damaging alkali/silica reaction.

Supersulfated cement consists of blast-furnace slag, at least 5 % anhydrite ($CaSO_4$), and a maximum of 5 wt % Portland cement clinker.

The use of *water-repellent cement* is advantageous, for example, in soil compaction. Water-repellent cement is a common Portland cement which contains small amounts of water-repellent substances added during grinding at elevated temperatures.

Oil-well cements are used for cementing the steel casing of gas and oil wells to the walls of the bore-hole and to seal porous formations. They are Portland and pozzolanic cements which set even at high temperatures and high pressure because of their composition.

Regulated-set cement, known in Japan as *Jet cement* and as *Schnellzement* in Germany, sets quickly and hardens very rapidly because of its high content of the aluminate compound $11\,CaO \cdot 7\,Al_2O_3 \cdot CaF_2$.

Expanding cement generally contains large amounts of aluminates and sulfates. The cement expands during hardening, by formation of ettringite.

Masonry cements are factory-produced binders for brickwork and plasterwork mortar with an adequate hydraulic strength development. Masonry cement is usually a mixture of Portland cement clinker, crushed rocks, and air entraining agents. These binders will be specified in a European Standard.

1.4. Clinker Production Process

1.4.1. Raw Materials

Portland cement clinker is the product which arises during the sintering process from a mixture of different raw material components and fuel ash. Both are fed to the kiln to give a mixture with the desired content of the main constituents CaO, SiO_2, Al_2O_3, Fe_2O_3, and MgO in the clinker. Attention also must be paid to minor constituents such as alkali metals, sulfates, chlorides, and trace elements.

The essential CaO-containing natural raw materials are limestone and chalk. The components SiO_2, Al_2O_3, and Fe_2O_3 are provided by addition of clay and quartz sand. The raw mix for cement clinker should contain 75 – 79 wt % $CaCO_3$ and 21 – 25 wt % clay. A natural mixture of the two is marl. Quality reasons allow only a small deviation in the total composition of the raw materials, including fuel ash. The target raw meal composition is calculated according to a multicomponent equation system using the hydraulic, siliceous, and aluminous deviations from given composition requirements (see Section 1.4.6).

Secondary raw materials can be employed if they meet the requirements on composition and environmental compatibility of the product, on other products properties, and on emission limits. Provisions must be made especially for the input of heavy metals. Therefore, quality assurance systems for the materials and the production process are advantageous. Examples for applicable secondary raw materials, grouped according to their main element, are given in the following [173]:

1) Ca group
   - Industrial lime
   - Lime sludge

2) Si group
   Used foundry sand
3) Fe group
   Roasted pyrite
   Synthetic hematite
   Red mud
4) Si – Al – Ca group
   Fly ashes
   Slags
   Crushed sand
5) S group
   Gypsum from flue gas desulfurization
   Chemical gypsum
6) F group
   CaF_2-containing filter mud

In the combined production of Portland cement and sulfuric acid (Müller – Kühne process), the mixture of raw materials may consist of anhydrite ($CaSO_4$), gypsum ($CaSO_4 \cdot 2\,H_2O$), clay, coke, other sulfite-, sulfate-, SiO_2-, Al_2O_3-, and Fe_2O_3-containing secondary raw materials, and fuels. The sulfur dioxide in the exhaust gas is converted into sulfuric acid by the usual processes (→ Sulfuric Acid and Sulfur Trioxide).

1.4.2. Mining of Raw Materials

Limestone, marl, and argillaceous limestone are usually quarried by blasting. The rocks are loaded onto heavy trucks by high-power excavators or bucket loaders and are transported to crushers of different construction. They are crushed in one or two stages to a particle size of < 30 mm. Mobile crushers that can follow the excavators along the working front are also employed. Soil type materials are torn away without blasting by caterpillars with bucket teeth and pushed toward the excavators. Chalk, marl, and clay are directly removed from the quarry site by using bucket-wheel or chain-bucket excavators.

The main prerequisite for the quality and uniformity of cement is that the composition of the raw materials before entering the kiln system meets the demands only with minor deviation over time. If the chemical composition of the different kinds of raw material varies greatly, then the broken raw material is often prehomogenized in rectangular or circular blending beds [5]. The blending beds generally contain a one-week supply of raw material, that is, 20 000 – 80 000 t. The material is subsequently reclaimed in the transverse direction of the pile. Variations in the deposits can be compensated by this measure to a blending efficiency of 70 – 90 %. By means of samples from the exploration of the deposit, samples taken during drilling, and samples taken during the build-up of the blending bed, the required average chemical composition can be regulated, following schemes which are optimized for each plant.

1.4.3. Grinding, Mixing, and Homogenization of Raw Materials

The raw materials are further processed to form a dry powder or a slurry.

Dry processing requires the fine grinding of the raw material constituents. The streams of raw materials are regulated by various kinds of dosage equipment. If necessary, corrective components such as quartz sand and iron ore can be added to obtain the desired chemical composition of the raw meal. During the grinding process, the mill feed is dried by hot gas, which is drawn through the mill in parallel flow. The waste heat of the exhaust gases from the kiln and/or exhaust air from the cooler is used for this purpose. Depending on the construction of the mill, raw material containing 8 – 12 wt % moisture can be dried. Supplementary firing is required in the case of a higher moisture content. Extremely moist raw materials are dried in a rotary dryer before they are ground. The residual moisture content in the raw meal must be less than 0.5 wt %.

Tube mills, high-pressure grinding rolls in combination with a deglomerator or a tube mill, and roller mills are employed to grind the raw materials. In tube mills, the material is ground by impact and friction with steel balls, in grinding rolls by high pressure, and in roller mills it is comminuted by pressure on a rotating pan by rollers. All grinding systems are equipped with separators and operate in a closed circuit. The separated coarse portions of the raw materials are fed back into the circuit. Roller mills require less energy and have a larger drying capacity than tube mills, but they are of limited use for very abrasive materials. Tube mills for raw meal have a diameter of up to 6 m and a capacity of up to 400 t/h. Their specific energy requirements

are around 12 – 16 kW h/t. Roller mills and high-pressure grinding rolls are built with throughput capacities of up to 400 t/h and specific energy requirements of about 10 – 14 kW h/t. High-pressure grinding rolls need a feed with a relatively low moisture content.

Wet processing is especially effective when the raw materials contain more that 20 wt % of water. The mixture of raw materials is ground in a tube mill with water addition to form a slurry.

The finished raw meal or slurry is continuously analyzed. Variations in chemical composition are compensated by adjusting the proportions of the constituents with correcting materials. Any remaining variations are equalized in homogenizing silos, which can hold the 8 – 10 h throughput of a mill. Homogenization is carried out by fluidizing the raw material powder with air and circulating it in a discontinuously operated fluidized bed. Alternatively the raw meal can be mechanically circulated through several silos or through a continuous blending silo. Raw materials slurry is homogenized by mechanical agitation or by using compressed air. Fluidizing and circulation of raw meal in discontinuous blending silos is the most effective method of homogenization, however, the power consumption is relatively high.

1.4.4. Fuels

Fuels for burning cement clinker are primarily hard coal, lignite, and petroleum coke, besides secondary fuels. Other fuels have only minor importance. The proportion of the different kinds of fuel is shown in Figure 4 [174]. The proportion, however, may vary from country to country, depending on the industrial and economic situation.

The substitution of fossil fuels by secondary fuels in general shows an increasing tendency. Suitable secondary fuels include used tires, waste oil, plastics, scrap wood, and burnable fractions from municipal waste and other materials. In general the energy content of common and secondary fuels is used in the clinker burning process in the sense of a materials-conversion process. As in the case of natural fuels, the mineral ashes are incorporated completely and become a part of the cement clinker. Therefore, cement clinker production ensures that both the energy and mineral content of waste materials are recovered in the rotary kiln. The simultaneous recovery of energy and ash distinguishes the clinker-burning process from combustion processes with the aim of energy conversion.

Figure 4. Proportions of the different kinds of fuels used for Portland cement clinker burning in 1998 (total consumption of thermal energy: 100.7×10^6 GJ) [C: Bunker C viscosity fuel oil; EL: Super light fuel oil]

Figure 5. Fuel-ash and clinker composition in the system $CaO - (Al_2O_3 + Fe_2O_3) - SiO_2$

The differences between clinker and ash composition are demonstrated in Figure 5 [175]. The calorific value and the ash composition of natural and secondary fuels vary in a wide range [164]. Depending on the kind, composition and portion of the ash component the raw feed composition has to be corrected properly to achieve unchanged clinker composition and hydraulic properties of the cements. Ashes rich in SiO_2 and Al_2O_3 need the existence and use of limestone deposits with $CaCO_3$ contents of more than 85 wt %.

1.4.5. Burning and Cooling

1.4.5.1. Technology

The production of cement belongs to the group of energy intensive industrial production processes. About 70 % of the total energy consumption is needed as thermal energy and 30 % as electrical energy (Fig. 6). Following the official federal statistics, in Germany the portion of energy costs of the net production cost value amounted to 24 % in 1998 [167]. Therefore, it was, and still is, necessary to decrease the energy consumption. This economic pressure has led to a marked change of technology in cement production, especially in the clinker burning process (see Section 1.4.5.2).

Figure 6. Proportion of thermal and electrical energy consumption in the cement production process (example)

In Europe, cement clinker is predominantly burnt in rotary kilns; shaft kilns are rarely used. *Rotary kilns* are refractory-lined tubes with a diameter (D) of up to about 6 m and of different length (L). They are inclined at an angle of 3 – 4° and rotate at 1.2 – 2 rpm. As a result of the inclination and rotation of the tube, the feed moves from the top of the kiln down the tube toward the coal-dust, oil, or gas flame. Near the flame, in the sintering zone of the rotary kiln with a gas temperature of 1800 – 2000 °C, the material reaches the temperatures of 1350 – 1500 °C necessary for the formation of clinker phases.

The energy released from fuel combustion in the rotary kiln is transferred to the material stream by radiation and convection. To ensure effective heat transfer in the temperature range below the clinkering temperature, the rotary kiln must be sufficiently long. In modern kiln systems, process steps such as drying and preheating of raw materials and precalcination are performed separately; hence the kiln can be shorter (L/D = 10 – 12). For comparison, the L/D ratio of long rotary kilns is 32 – 35.

The largest kilns have lengths of more than 200 m. Long kilns, without grate or suspension preheaters and with clinker capacities of more than 3000 t/d, are used in both the wet and dry process. They are known for their simplicity and their operating reliability. The upper part of the long kilns is equipped with chain curtains and fixed installations to improve the heat transfer for drying and preheating the raw material. Whereas the wet process requires 5000 – 6000 kJ/kg of clinker, the corresponding figure for the dry process is 3400 – 5000 kJ/kg. This is because besides increased energy losses (waste gas and kiln wall) additional energy is needed for water evaporation.

Rotary kilns equipped with preheaters have an L/D ratio of 10 – 17. With 3100 – 4200 kJ/kg clinker, they need a considerably lower input of thermal energy. According to CEMBUREAU (Association of the European Cement Industry) statistics, the proportion of clinker produced in dry-process kilns equipped with preheater and calcinator is increasing. Figure 7 shows the European status as of 1992 [176]. In Germany the proportion of energy-saving suspension preheater kiln systems increased to 84 % in 1998. The grate preheater system dropped to 14 % and long wet-process kilns were shut down completely.

Figure 7. Portland cement clinker production in Europe broken down according to different process technologies (CEMBUREAU statistics 1992) [SP: Suspension typ preheater kilns, dry process]

Two types of preheater exist: grate and suspension preheaters. Grate preheaters are fed with pellets or briquettes. Pellets are formed from raw meal, wetted with about 12 wt % water in a pelletizer (semidry process). The cylinder-shaped briquettes are prepared from a raw material slurry, which is dewatered in a mechanical filter press and subsequently extruded in a screen compactor (semi-wet process).

Figure 8. Schematic of clinker burning in a grate-preheater kiln system with grate cooler [177]
a) Pelletizer; b) Intermediate dust collector; c) Drying chamber; d) Hot chamber; e) Grate; f) Rotary kiln; g) Burner; h) Grate cooler; i) Clinker belt

In the grate-preheater kiln (Fig. 8), pellets or briquettes of the feed material are placed on a grate. The compartment is separated into a hot gas chamber and a drying chamber by a partition wall with an opening for the grate. The first fan draws the exhaust gas from the rotary kiln into the top of the preheater, through the pellet layer in the hot gas chamber, and then through the cyclones of the intermediate dust collector. In these cyclones, large dust particles have to be removed to avoid damage to the fan. The second fan then draws the gas into the top of the drying chamber, through the layer of moist pellets, and finally into the dust collector.

The process gas leaves the rotary kiln with a temperature of 1000 – 1200 °C. On passing through the hot gas chamber, the process gas is cooled to 250 – 300 °C, and it leaves the drying chamber at 90 – 150 °C. The low temperature (60 – 90 K above the water dew point) is due to the energy consumption for pellet drying. As a result of its intensive contact with the process gas, the feed reaches a temperature of about 150 °C in the drying chamber and about 800 °C in the heating chamber. The largest grate preheater kilns have a clinker capacity of more than 3000 t/d.

The suspension preheater kilns show a great variety in construction. In principle, the preheater consists of four cyclone stages which are arranged one above the other in a 50 – 70 m high tower (Fig. 9). New kilns also can be equipped with five or six stages, depending on the heat demand for raw material drying. The uppermost stage comprises two parallel cyclones for better dust separation. The process gases from the rotary kiln move through the cyclone stages in countercurrent flow to the raw material feed. The dry raw material is added to the exhaust gas in the riser duct before the uppermost cyclone stage. It is separated from the gas in the cyclones and re-mixed with the exhaust gas from the next cyclone stage. This procedure is repeated until the material, preheated to about 800 – 850 °C, is fed to the calcinator and/or the kiln. This procedure leads to an intensive heat transfer.

Further development of the preheater kiln system led to the introduction of the precalcination technique around 1970. In this process calcination of the raw feed has been shifted from the upper end of the rotary kiln to the calciner/preheater. Hence, the total thermal energy input had to be split up into two burning locations: the primary burner in the sintering zone and a secondary burning system (calciner) between rotary kiln and the lowest preheater stage. The energy input by the secondary burning system can be high enough to calcine 70 – 90 % of the $CaCO_3$ in the raw feed before it enters the rotary kiln. In conventional systems without a secondary burner the thermal energy for the dissociation of $CaCO_3$ is released completely by the primary burner, and the raw feed is calcined by only 40 – 50 % before it enters the kiln.

The major advantage of the precalcination process is that the majority of the energy re-

quired for $CaCO_3$ dissociation is released in the calciner by flameless combustion at about 900 °C. For this reason, low-grade materials such as ash-rich coal and waste material can be used as secondary fuels, provided the ash content can be compensated in the raw feed composition. For a given kiln dimension, precalcination increases the clinker production capacity. The largest clinker capacities of the suspension preheater kilns with precalcination amount to 8000 – 10 000 t/d.

Figure 9. Schematic of clinker burning in a four-stage suspension preheater kiln system with grate cooler [177]
a) Preheater; b) Calciner; c) Tertiary air duct; d) Rotary kiln; e) Grate cooler

The temperature of the exhaust gas leaving a 4-stage preheater is as high as 380 °C, and it can be used to dry raw materials with a moisture content of about 8 – 10 wt %, as well as coal. In the case of raw materials with a lower moisture content than about 5 wt %, it may be economic to partly recover the heat of the preheater gas, for example by installing a waste-heat boiler [174].

Calciners exist in different designs [178], [179]. Besides precalcination the equipment additionally offers the possibility for a stepped fuel and/or raw material input. Staged combustion is already successfully being used to reduce the thermal NO_x load in the kiln exhaust gas by using sub-stoichiometric burning conditions in the first calciner step. The combustion air which is necessary to burn the secondary fuel is supplied by transport through the rotary kiln and/or by a separate tertiary air duct. Figure 10 shows a calciner combustion air supply with and without a tertiary air duct [177]. After the reduction phase the exhaust gas flow is mixed with tertiary air to burn out, for example, carbon monoxide [167].

The clinker leaves the rotary kiln after being sintered at about 1150 – 1350 °C and enters a grate, tube, or planetary cooler, in which it is cooled in countercurrent or cross/countercurrent flow. Figure 11 shows the different cooler types. In the grate coolers of different construction, the clinker is transported on a moving or on a combination of stationary and moving grates. In the grate, tube, and planetary or satellite cooler (which consists of 10 or 11 tube coolers, attached to the circumference of the rotary kiln), the hot parts are equipped with refractories. Additionally, tube and satellite coolers are constructed with air-lifting systems to improve the heat exchange. The heated cooling air is used completely or to a great extent as so-called secondary or tertiary air, which is fed back into the sintering zone of the kiln or into the calcinator as preheated combustion air at 700 – 1000 °C. Grate coolers require more cooling air than is necessary for combustion. The excess air volume leaves the system as waste air at about 250 – 350 °C. After cooling, the clinker has a temperature of 80 – 200 °C. In modern kiln systems most of the waste gas heat and the heat of the clinker can be recovered. The efficiency of energy use has thus increased by more than 70 %.

The formation of alkali metal, sulfur, chloride, and heavy metal cycles can be diminished by a bypass arrangement, if necessary. For this purpose, a partial volume of dust- and vapors-containing kiln exhaust gas is separated from the main stream before it enters the calciner and/or the preheater [180]. However, a bypass increases the energy loss of a kiln system, it needs special waste-gas cleaning equipment, and leads to waste materials, which in most cases must be disposed of.

1.4.5.2. Energy Consumption

Thermal energy is spent more or less exclusively for burning clinker. The change from processes with a high specific energy demand to energy-saving processes has led to a remarkable decrease in thermal energy consumption. Figure 12 shows the development in Germany since 1950. The average demand of about 3500 kJ/kg clinker in 1998 is the result of continuous and long-term improvements in process technology and energy efficiency which additionally need a permanent capital investment [174]. The benefits of process conversion are also obvious for other European countries [176].

Figure 12. Development of the specific thermal energy consumption in Germany since 1950 [174]

The approximately constant expenditure of thermal energy for the drying of raw materials (average moisture content 5 – 8 wt %) and the energy demand for chemical reactions (1700 kJ/kg clinker) are unavoidable for natural raw material components. Experience has shown that technical measures to improve the burning process in many cases are exhausted, so that the fur-

ther energy saving potential in general seems to be small [176]. The utilization of electrical energy saving processes in the comminution of raw materials, coal, and especially cement has the favorable effect that the total specific consumption at present is not increasing in a marked way. Due to growing requirements on the performance of cements, e.g., higher fineness and strength, on a higher proportion of cements with other main constituents besides clinker, or on measures which continue the decrease of particulate and gaseous emissions, a rising consumption of electrical energy must be expected. This applies also to technologies which are based on the production of low-energy (C_2S) clinker or on burning processes with mineralizers.

Figure 13. Decomposition of raw material components and formation of clinker phases with increasing temperature [181]

The energy-saving potential of the cement production process is summarized in the following:

1) Optimization of the burning process
   – Dry process (precalcination, grate cooler)
   – Waste gas utilization
   – Process control
   – Burnability (LSF, low energy clinker, mineralizers)
   – Secondary raw materials and fuels
2) Optimization of the grinding process
   – Primary crushing
   – High-pressure comminution (roller mill, high-pressure grinding rolls)
   – High-capacity separator
3) Utilization of different main constituents in cement

1.4.5.3. Thermochemistry of the Burning Process

Several chemical reactions occur during the heating of raw materials to produce cement clinker. Carbon dioxide and water vapor, released from limestone and clay, enter the waste gas stream derived from the burning of fuel and affect its composition. Figure 13 shows schematically the reactions taking place with increasing temperature and the reaction products [181].

Accordingly, the clinker-burning process can be subdivided into six temperature-dependent steps:

1) Starting composition (20 °C): Calcite ($CaCO_3$), quartz (SiO_2), clay minerals ($SiO_2 - Al_2O_3 - H_2O$), iron-containing components (Fe_2O_3)
2) Temperature range 20 – 700 °C (preheater): liquid water and adsorbed water escape during initial heating, followed by dehydration of clay minerals, and activation of oxides by decomposition of clay minerals.
3) Temperature range 760 – 900 °C (preheater and calciner): Calcination of $CaCO_3$, binding of activated Al_2O_3, SiO_2, and Fe_2O_3; first formation of clinker phases such as C_2S, $C_2(A,F)$, $C_{12}A_7$, (CA).
4) Temperature range 900 – 1250 °C (kiln): completion of C_2S formation, initial formation of melt (C_3A).
5) Temperature range 1250 – 1450 °C (kiln): starting at 1250 °C and activated by the melt, C_3S is formed from CaO and C_2S.
6) Cooling step (not shown in Fig. 13): cooling of the clinker commences in the precooling zone of the kiln. The length of this zone and the cooling rate depend on several factors, for example, on the primary burner position and the type of cooler. The clinker leaves the kiln at a temperature of about 1350 °C (sintering zone close to the kiln exit) to 1150 °C (long cooling zone for satellite coolers). The optimization of cooler efficiency by new techniques improves the efficiency of the whole kiln system [182]. Additionally, the clinker and cement properties can be influenced positively by a high cooling rate, especially in the precooling area of the kiln [183].

Table 5. Energy demand of various clinker burning processes [167]

	Suspension preheater kiln	Grate preheater kiln	Long wet process kiln	Long dry process kiln
Percentage of total consumption				
Clinker formation	52.5	47.2	30.5	34.6
Evaporation of water	0.5	16.1	41.5	0.4
Waste gas (after preheater)	25.5	7.8	13.2	47.8
Exhausted cooler air	8.8	5.8	1.8	1.7
Residual heat of the clinker	2.4	1.8	1.0	1.2
Radiation and other wall losses	7.5	11.9	9.5	11.8
Others	2.8	9.4	2.5	2.5
Total thermal energy consumption, kJ/kg clinker	3000 – 3800	3100 – 3800	5000 – 6000	5100
Electrical energy demand (kiln system), kW h/t clinker	10 – 20	12 – 20	10 – 20	17

The total amount of energy required to burn cement clinker comprises several components. The theoretical energy demand of clinker formation is the difference in enthalpy between the product (clinker) and the reacting raw materials [29]. The complete balance of the thermal energy consumption additionally involves the fraction of energy losses. Both the theoretical energy demand and the losses are equivalent to the fuel demand. Energy losses are caused by evaporation of water, exhaust gas, wall losses of the preheater, kiln, and cooler, and residual heat of the hot clinker. Table 5 shows characteristic examples of energy balances and the distribution of losses for different burning processes [167].

The dehydration and decomposition of the clay minerals and the calcination of calcium and magnesium carbonate are endothermic reactions. The formation of clinker phases from calcium oxide and the decomposition products of the clay components involves exothermic reactions. Hence, the theoretical energy requirements depend on the chemical and mineral composition of the raw material mixture and amount to 1600 – 1900 kJ/kg clinker.

The theoretical energy demand for clinker burning is mainly dependent on the amount of energy required for $CaCO_3$ calcination (1780 kJ/kg). A change in the raw meal composition therefore influences the theoretical energy demand. The value can be significantly decreased by utilization of raw feed with a lower $CaCO_3$ content or with a standard lime factor of less than 92. As a consequence of these measures, the thermal energy consumption, the sintering temperature, and also the formation of thermal NO_x decrease. However, the increasing C_2S content (Belite clinker), the higher electrical energy demand for grinding, and the loss in strength under industrial production conditions are unfavorable [167]. The utilization of siliceous or calcareous fly ashes and granulated blast-furnace slag as constituents of the raw mix can decrease the theoretical energy demand.

The kinetics of raw meal decomposition and of the formation of clinker phases depend not only on the composition and burning temperature but also on the partial pressure of CO_2, the fineness and crystallinity of $CaCO_3$, the degree of homogeneity in the distribution of quartz among clay minerals and $CaCO_3$, on the fineness of quartz, the heating velocity, and on mineralizers and fluxes, which influence the amount and viscosity of the clinker melt. Figure 14 shows the particle size distribution of constituents in raw meal of different geological origin [184]. Size distribution and the homogeneity of the distribution are of technical importance. They are often summarized under the term ″burnability″ of a cement clinker raw mix [180].

1.4.6. Characterization of Cement Clinker
